ABSTRACT

Methanogens utilize an unusual energy-conserving electron transport chain that involves reduction of a limited number of electron acceptors to methane (CH₄) gas. Previous biochemical studies suggest that the proton pumping F₄₂₀H₂ dehydrogenase (Fpo) plays a crucial role in this process during growth on methanol. However, *Methanosarcina barkeri* Δfpo mutants investigated in Chapter 2 display no measurable phenotype on this substrate. In contrast, Δfrh mutants lacking the cytoplasmic F₄₂₀-dependent hydrogenase (Frh) are severely affected in their ability to grow and make methane from methanol, while double $\Delta fpo \Delta frh$ mutants are completely unable to utilize this substrate. These data suggest that while *M. barkeri* has the flexibility to use the Fpo-dependent electron transport chain when needed, the preferred energy conservation pathway involves production of H₂ gas by Frh hydrogenase within the cytoplasm. The H₂ can then diffuse out of the cell, where it can be oxidized by the periplasmic methanophenazine-dependent hydrogenase (Vht), with transfer of electrons into the electron transport chain. Consistent with this “H₂-cycling” proposal, a conditional *vht* mutant isolated in Chapter 3, is unable to grow using any of the methanogenic substrates tested under non-permissive conditions, suggesting that Vht is essential for growth of *M. barkeri*. Moreover, repression of *vht* expression results in a rapid increase in H₂ partial pressure, which supports the hypothesis that Vht is required for H₂ uptake. H₂ accumulation in the culture headspace of conditional *vht* mutant is accompanied with cessation

of methanogenesis and growth, implying that H₂ uptake is essential for anaerobic respiration and viability. In contrast, Vht is not essential in mutants lacking the H₂-producing Frh hydrogenase. This is consistent with the hypothesis that Vht is required for H₂ uptake, only when Frh produces H₂, that is, Frh and Vht hydrogenases are functionally coupled in a “H₂-cycling” energy conservation mechanism. Because production of H₂ by Frh consumes protons within the cytoplasm and oxidation of H₂ by Vht releases protons outside the cell, this electron transport chain is capable of establishing a trans-membrane proton gradient that can be used to make ATP by the ATP synthase. Our study provides the first direct experimental evidence for H₂-cycling, since it was proposed to be involved in energy conservation in sulfate-reducing bacteria in 1981.

To further dissect the roles of these hydrogenases in *M. barkeri* physiology, I constructed a series of hydrogenase deletion mutants in various combinations in Chapter 4, including a mutant that is devoid of all three types of hydrogenases, ferredoxin-dependent Ech, Frh and Vht. My data show that each of the three types of hydrogenases is needed for growth via the CO₂ reduction pathway. In contrast, none of the hydrogenases is essential during methylotrophic growth, indicating the presence of H₂-independent electron transport chains, which are able to support wild-type growth yields. Either Vht or Ech hydrogenase alone can support growth using the methyl respiration pathway. However, both Ech and Vht hydrogenases are required for acetate utilization. The data presented in chapter 4 also suggest that Ech and/or Frh hydrogenases block the methyl oxidative pathway by catalyzing conversion of H₂

to Fd_{red} and F₄₂₀H₂, respectively. In addition, evidence is provided for involvement of Hyp proteins in maturation of Ech hydrogenase. This work highlights the similarities and differences between H₂-independent electron transport chains of the hydrogenotroph *M. barkeri* and the non-hydrogenotroph *Methanosarcina acetivorans*.

ACKNOWLEDGEMENTS

I would like to express my sincerest gratitude to the following people. Prof. Bill Metcalf, my advisor, for his support and guidance. I am eternally grateful to him for letting me be a part of his lab and mentoring me patiently throughout the course of this study. Members of my thesis committee: Prof. John Cronan, Prof. Andrei Kuzminov, Prof. Brenda Wilson and Prof. Gary Olsen, for their suggestions and help. Head, Staff and Faculty at the Department of Microbiology, for making this a smooth ride for me. All members of the Metcalf group, for their encouragement and companionship. Prof. Ralph Wolfe, for being an inspiration.

My friends, especially Lara Rajeev, Arpita Bose and Rina Opulencia. They were my family during the graduate school.

My parents, who instilled in me the importance of education and stood by my side through thick and thin. My brother, who always encourages me to be better and more confident. My husband, who believes in me and is always there for me.

This work is dedicated to:
my parents, Aai and Baba
my brother, Tushar
and my husband, Monik

CHAPTER 1

INTRODUCTION

1.1 METHANOGENESIS: DEFINITION AND IMPORTANCE

Methanogenesis is defined as the production of methane (CH₄) gas. Under reducing hydrothermal conditions, typical of Earth's crust, metal-rich minerals catalyze abiogenic methane production from carbonates (geogenesis) (47, 109). However, majority of methane on earth is derived from organic matter through thermal decomposition (thermogenesis), microbial metabolism or combustion of biomass and fossil fuels (ignigenesis) (93, 109). Among these, microbially mediated methane production is the most prevalent, accounting for 2.4×10^{15} g of methane production annually from natural and anthropogenic sources (106). The former include marine and freshwater sediments, swamps and intestinal tracts of ruminants and termites (106), whereas landfills, animal husbandry, rice cultivation and waste management constitute man-made sources (2).

Over the last two hundred and fifty years, atmospheric concentration of methane has increased by about 143%, to reach 1,774 ppb in 2005 (2). Moreover, its concentration is rising further at an annual rate of 0.9% (59). This is of major concern as methane is a greenhouse gas that is 21 times more potent than carbon dioxide (CO₂) and has therefore been implicated in global warming. As more than half of the current methane flux to the atmosphere is estimated to

be anthropogenic, serious efforts are underway to mitigate methane emissions and harvest methane gas for use as an energy source (1, 2).

Methane is a clean, renewable energy source. It is the primary component of natural gas, which is extensively used for domestic and industrial purposes (1). Enormous amount of methane is also sequestered in the form of methane hydrates, which are cages of water molecules that enclose methane gas, most of which is produced biologically. These structures are stable at high pressures and low temperatures that occur in permafrost regions and within ocean floor sediments 500 m below sea level. Methane hydrates represent one of the largest hydrocarbon sources on Earth ($>10^{19}$ g) and if tapped for methane, could potentially ensure long-term energy security. However, release of methane from the hydrates may also contribute to global warming (23, 59, 106).

Methanogenesis is a major player in the global carbon cycle as it represents the terminal step in biomass degradation in many anoxic habitats (Figure 1.1). In these environments, mineralization of organic matter is initiated by hydrolysis of biopolymers to monomers and lipids to glycerol and long chain fatty acids by bacteria, protozoa and fungi. In conjunction with syntrophic bacteria, these anaerobes further ferment the compounds to acetic acid, CO_2 and hydrogen (H_2), which are substrates for methane formation. Nearly half of the total methane produced by methanogenesis (10^{15} g) is oxidized by anaerobic archaea and bacteria to CO_2 . The other half seeps into the aerobic zone, where aerobic bacteria oxidize about 60% of it. The rest of methane ends up in the atmosphere, where it is photo-oxidized to CO_2 . The formation of CO_2 completes

the carbon cycle, as it can be once again fixed into organic matter by photosynthesis (106).

Figure 1.1 Methane (CH₄) as an intermediate in the global carbon cycle. Continuous arrows indicate a reaction and dashed arrows indicate diffusion and/or convection. In anoxic environments (for example, freshwater sediments, swamps, paddy fields, land fills and the intestinal tracts of ruminants and termites), approximately 1 giga ton (Gt) of methane (10¹⁵ g) is formed per year from acetate, carbon dioxide (CO₂) and hydrogen (H₂) through the metabolic activity of methanogenic archaea. Almost the same amount of methane is released into the environment from melting methane hydrates. From the 2 Gt of methane that is produced per year, ~0.6 Gt is oxidized to CO₂ by aerobic bacteria, ~1 Gt is oxidized by anaerobic archaea and ~0.4 Gt escapes into the atmosphere. Another 0.2 Gt per year is released into the atmosphere from other sources, such as gas-pipe leakages and the burning of biomass. In the atmosphere, most of the methane is photo-oxidized to CO₂. Only 0.03 Gt per year is removed from the atmosphere by aerobic bacteria that live in soils and water. Figure created from (106).

Operation of a similar food chain in anaerobic digesters allows treatment of organic wastes such as sewage sludge, animal manure, crop wastes and

municipal wastes (116). The methane thus produced provides sufficient energy to run a sewage treatment plant (94). Some methane-producing organisms that have the ability to degrade halogenated organic compounds can be potentially used in anaerobic digesters for bioremediation (75).

1.2 ECOLOGY OF METHANOGENS

Methane is produced as a byproduct of respiration by a group of strictly anaerobic organisms called methanogens (22). These organisms are abundant in anoxic habitats where electron acceptors such as NO_3^- , SO_4^{2-} , Fe^{3+} and Mn^{4+} are limiting. As reduction of these electron acceptors is thermodynamically more favorable than CO_2 reduction to methane, methanogens are usually out-competed by bacteria that utilize them (denitrifiers, sulfate-reducing bacteria, iron-reducing bacteria and manganese-reducers) (106). Common methanogenic habitats include wetlands, oceans, gastrointestinal tracts, anaerobic digestors, landfills and rice paddies (64).

Methanogens can be found in a range of salinities from freshwater to hypersaline (116). In marine sediments, where sulfate concentrations are 20-30 mM, sulfate-reducers out-compete methanogens for H_2 and acetate. Thus, methanogens resort to utilization of methylated compounds, which are not used efficiently by sulfate-reducing bacteria. Hydrogenotrophic methanogens isolated from marine environments are found below the sulfate-reducing zones and are possibly associated in syntrophic growth with H_2 -producers. In marine sediments rich in organic matter, H_2 and acetate may become available for methanogenesis

once sulfate pools have been depleted. In freshwater environments, which have low sulfate concentrations (100-200 μM), methanogenesis can occur from both CO_2 and acetate. Nearly three-fourths of methane in these environments originates from acetate (64).

Methanogens are distributed over a wide range of temperatures. psychrophilic species like *Methanococcoides burtonii* and *Methanogenium frigidum* have been isolated from a frozen lake in Antarctica (1-2°C) (91). In contrast, extremely hot environments like hydrothermal vents (110°C) were the source of methanogens like *Methanopyrus kandleri* (99) and *Methanocaldococcus jannaschii* (37). Many methanogens are also mesophilic like *Methanosarcina barkeri* and *Methanococcus maripaludis* (91).

Most methanogens have pH optima near neutrality. However, methanogenesis has been detected in acidic peat bogs with a pH of 3 (116) and in alkaline lakes with a pH of 9.7 (14). A recent isolate from a minerotrophic fen, *Methanosphaerula palustris*, can grow at pH 4.8 – 6.4 (16). Other acidophilic species like *Methanobacterium espanolae* (86) and *Methanobrevibacter acidurans* (92) are capable of growth at pH 5.2 – 6.2. Alkaliphilic methanogens that can grow at pH 9.2, *Methanohalophilus oregonense* (14) and *Methanohalophilus zhilinae* (71), have also been isolated.

1.3 PHYLOGENY OF METHANOGENS

On the basis of their 16s rRNA sequences, methanogens were placed in a phylogenetic group distinct from Bacteria and Eukarya, called Archaea (114). Among the unique features that set Archaea apart are, lipids composed of

isoprenoid alcohols that are ether linked to glycerol, rather than ester linked fatty acids present in Bacteria and Eukarya; and cell walls that are made of pseudomurein, proteins or glycoproteins, instead of bacterial peptidoglycan. Although Archaea resemble Bacteria in their cellular and genomic organization, their transcription and translation machinery is similar to that from Eukarya. Thus Archaea exhibit Eukaryal-like RNA polymerase sensitivity and subunit structure, ribosomal proteins, initiator methionine for protein synthesis and elongation factor EF-2 (113).

Methanogens are a phylogenetically diverse group belonging to the kingdom Euryarchaeota. Based on their 16S rRNA sequence similarity, cell envelope structure, lipid composition, substrate range and other biological properties, they have been classified into five orders: *Methanobacteriales*, *Methanococcales*, *Methanomicrobiales*, *Methanosarcinales* and *Methanopyrales* (64).

Members of the order *Methanobacteriales* produce methane by reducing CO₂ with a variety of electron donors: H₂, formate, CO and secondary alcohols, of which H₂ is used most commonly. They are rod-shaped, often filamentous and non-motile with a pseudomurein-containing cell wall and caldarchaeol, archaeol and hydroxyarchaeol as core lipids (55). The order is divided into two families, Methanobacteriaceae and Methanothermaceae. The former contains three mesophilic genera, *Methanobacterium*, *Methanobrevibacter* and *Methanosphaera*, and one extremely thermophilic genus *Methanothermobacter*. Interestingly, *Methanosphaera* cannot use CO₂ as a terminal electron acceptor

and instead reduces methanol to methane using H_2 . The hyperthermophilic genus *Methanothermus* is the sole member of Methanothermaceae and unlike other members of this order, is motile (64).

Methanogens within the order *Methanococcales* use H_2 or formate as electron donors for CO_2 reduction. They are cocci, motile and contain S-layer proteins in cell walls. Their lipids are composed of archaeol, caldarchaeol, hydroxyarchaeol and macrocyclic archaeal. This order comprises two families, the first of which is Methanocaldococcaceae that contains the hyperthermophilic genera, *Methanocaldococcus* and *Methanotorris*. The mesophilic genus *Methanococcus* and the extremely thermophilic genus *Methanothermococcus*, belong to the second family Methanococcaceae. All these genera have been isolated from marine habitats and require sea salts for optimal growth (64).

Although all *Methanomicrobiales* members are able to reduce CO_2 using H_2 gas as the electron donor, most of them can also use formate and many can employ secondary alcohols as reductants. Morphology (cocci, rods or sheathed rods) and motility varies between species. Their cell walls are made of proteins or glycoproteins, and lipids of archaeol and cardarchaeol. The order has three families, Methanomicrobiaceae, Methanocorpusculaceae and Methanospirillaceae. These families are further divided into nine genera (64).

The order *Methanopyrales* is represented by only one species, *Methanopyrus kandleri*, which belongs to the family Methanopyraceae. This hyperthermophilic species uses H_2 plus CO_2 to make methane. It is rod-shaped and motile, with pseudomurein-containing cell wall and archaeol as lipids (64).

Members of the order *Methanosarcinales* can use methylated compounds, acetate and/or CO₂ plus H₂ for methanogenesis. Thus, they are metabolically the most versatile methanogens. They are non-motile and occur as cocci, pseudosarcinae or sheathed rods. Most cells have a protein cell wall, whereas some are also surrounded by a sheath of acidic heteropolysaccharides. Their lipids contain archaeol, caldarchaeol and hydroxyarchaeol. The order is divided into two families, Methanosaetaceae and Methanosarcinaceae (64).

Methanosaetaceae is represented by only one genus, *Methanosaeta*, which uses only acetate for methane production. The family Methanosarcinaceae has 8 genera and is characterized by the ability of its members to use methylated compounds like methanol, methylamines and methylsulfides as methanogenic substrates (64). Although some species of the genus *Methanosarcina* like *M. barkeri* are able to reduce CO₂ with H₂, they are unable to compete with other hydrogenotrophic methanogens for H₂. This is because they have a 10-fold higher H₂ threshold concentration than hydrogenotrophic methanogens that are only able to use this substrate, i.e. hydrogenotrophic specialists like *Methanospirillum* or *Methanobacterium* (106). In contrast, generalists like *Methanosarcina* that have the ability to utilize a variety of substrates, exhibit faster growth rates and higher yields at high substrate concentrations, but are out-competed at lower concentrations due to lower affinities for the substrates. This case is further exemplified by the inability of *Methanosarcina* to compete with *Methanosaeta* for acetate, when the substrate is present at low concentrations. (116).

The work in this thesis focuses on *Methanosarcina* species, in particular *M. barkeri* Fusaro, which was isolated from a freshwater coastal lagoon called Lago Del Fusaro in Italy. Another freshwater species, *M. mazei* Gö1, was isolated from sewage sludge (69). Both these species have the widest substrate range among methanogens, being able to use CO₂ plus H₂, methylated compounds and acetate (48, 106). On the other hand, *M. acetivorans* C2A that was isolated from the sediment of a marine canyon in California is capable of using all these substrates except CO₂ plus H₂. Interestingly, *M. barkeri* and *M. acetivorans* can also utilize CO (64). Whole genome sequences are available for all species mentioned above (26, 33, 69). All *Methanosarcina* species are mesophilic and halotolerant, except *M. thermophila* that is moderately thermophilic (17) and *M. siciliae* that is slightly halophilic (81). Also, *M. lacustris* isolated from lake sediment in Switzerland (97) and *M. baltica* isolated from the Baltic sea (112), are psychrotolerant. Other species include *M. semesiae*, which is a dimethylsulfide-utilizing methanogen from a mangrove sediment in Tanzania (68) and *M. vacuolata*, which is a gas vacuolated species isolated from an anaerobic digester in Moscow (115).

1.4 METHANOGENIC SUBSTRATES AND PATHWAYS

Although only two genera (*Methanosaeta* and *Methanosarcina*) are able to utilize acetate, these organisms account for nearly two-thirds of biological methane production (31, 64). The remaining one-third is derived primarily from reduction of CO₂ with H₂ or formate by most methanogens (31). All these

methanogenic substrates occur as major fermentation products in many anaerobic habitats (116). A fraction of methane also comes from the methyl groups of methylated compounds, which are formed from osmolytes of marine bacteria, algae, phytoplankton and plants. These compounds include methanol, methylated amines (tetramethylammonium, trimethylamine, dimethylamine and monomethylamine) and methylated sulfides (methanethiol and dimethylsulfide) (64). Methanol arises from the cleavage of methylated compounds such as pectin and lignin (98, 116). Anaerobic breakdown of methylated amino compounds such as choline and betaine gives rise to methylated amines (116). Methylated sulfides are derived from sulfur-containing amino acids like methionine or methylation of sulfide or methanethiol (65, 116). Production of these compounds has also been reported in methanogen cultures, including *M. acetivorans* (77).

Methanogenesis proceeds from the aforementioned substrates via four distinct but overlapping pathways (Table 1.1): 1) CO₂ reduction or hydrogenotrophic pathway, in which CO₂ is reduced to methane using electrons from H₂; 2) Aceticlastic pathway, wherein methyl group of acetate is reduced to methane using electrons derived from oxidation of its carbonyl group; 3) Methylotrophic pathway involves oxidation of a quarter of methyl groups of methylated compounds to provide electrons for reduction of the rest of the methyl groups to methane (29); and 4) Methyl respiration pathway, in which methyl group of methylated compounds is reduced to methane using electrons from H₂ (76).

Table 1.1 The overall reaction and energy yield from the four methanogenic pathways (11, 64, 105)

Pathway	Reaction	ΔG° (kJ/mol)	ΔG° (kJ/mol substrate)
CO ₂ reduction	$\text{CO}_2 + 4\text{H}_2 \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$	-131	-131
Aceticlastic	$\text{CH}_3\text{COOH} \rightarrow \text{CH}_4 + \text{CO}_2$	-33	-33
Methylotrophic	$4\text{CH}_3\text{OH} \rightarrow 3\text{CH}_4 + \text{CO}_2 + 2\text{H}_2\text{O}$	-106	-27
	$4(\text{CH}_3)_3\text{N} + 6\text{H}_2\text{O} \rightarrow 9\text{CH}_4 + 3\text{CO}_2 + 4\text{NH}_3$	-74	-19
	$2(\text{CH}_3)_2\text{NH} + 2\text{H}_2\text{O} \rightarrow 3\text{CH}_4 + \text{CO}_2 + 2\text{NH}_3$	-73	-18
	$4\text{CH}_3\text{NH}_2 + 2\text{H}_2\text{O} \rightarrow 3\text{CH}_4 + \text{CO}_2 + 4\text{NH}_3$	-75	-19
	$2(\text{CH}_3)_2\text{S} + 2\text{H}_2\text{O} \rightarrow 3\text{CH}_4 + \text{CO}_2 + 2\text{H}_2\text{S}$	-49	-25
Methyl respiration	$\text{CH}_3\text{OH} + \text{H}_2 \rightarrow \text{CH}_4 + \text{H}_2\text{O}$	-113	-113

1.4.1 CO₂ reduction pathway

In this pathway (reviewed in (64, 104)), CO₂ initially binds to the coenzyme methanofuran (MF) and is reduced to the formyl level by formyl-MF dehydrogenase (Fmd) using electrons from reduced ferredoxin (Fd_{red}) (Figure

1.2). In *M. barkeri*, the Ech hydrogenase has been proposed to catalyze the endergonic electron transfer from H_2 to ferredoxin (Fd_{ox}) by virtue of reverse

Figure 1.2 CO₂-reduction pathway. Many methanogens reduce CO₂ to methane using electrons derived from the oxidation of H₂. Steps not required in this pathway are shaded in gray. Abbreviations: CHO-MF, formyl-methanofuran; CHO-H₄MPT, formyl-tetrahydromethanopterin; CH≡H₄MPT, methenyl-tetrahydromethanopterin; CH₂=H₄MPT, methylene-tetrahydromethanopterin; CH₃-H₄MPT, methyl-tetrahydromethanopterin; CH₃-S-CoM, methyl-coenzyme M; CoM-SH, coenzyme M; CoB-SH, coenzyme B; CoM-S-S-CoB, heterodisulfide of CoM-SH and CoB-SH; MP/MPH₂, oxidized and reduced methanophenazine; F₄₂₀/F₄₂₀H₂, oxidized and reduced Factor 420; Fd_{ox}/Fd_{red}, oxidized and reduced ferredoxin; Ech, ferredoxin-dependent hydrogenase; Frh, F₄₂₀-dependent hydrogenase; Vht, methanophenazine-dependent hydrogenase; Fpo, F₄₂₀H₂ dehydrogenase; Hdr, heterodisulfide reductase; Fmd, formyl-MF dehydrogenase; Ftr, formyl-MF:H₄MPT formyltransferase; Mch, methenyl-H₄MPT cyclohydrolase; Mtd, methylene-H₄MPT dehydrogenase; Mer, methylene-H₄MPT reductase; Mtr, methyl-H₄MPT:CoM methyltransferase; Mcr, methyl-S-CoM reductase. Figure adapted from (39).

electron transport (72, 73). The formyl group is then transferred to the coenzyme tetrahydromethanopterin (H_4MPT) by formyl-MF: H_4MPT formyltransferase (Ftr). This is followed by dehydration of formyl- H_4MPT to methenyl- H_4MPT by methenyl- H_4MPT cyclohydrolase (Mch). Methenyl- H_4MPT is first reduced to methylene- H_4MPT by methylene- H_4MPT dehydrogenase (Mtd) and then to methyl- H_4MPT by methylene- H_4MPT reductase (Mer). Both reactions use reduced coenzyme F_{420} ($F_{420}H_2$) as the electron donor, which is produced from H_2 by the F_{420} -reducing hydrogenase (Frh) (32). In many methanogens like *Methanothermobacter marburgensis* and *M. maripaludis*, methenyl-group reduction can also be catalyzed with H_2 by a cytoplasmic iron-sulfur cluster-free hydrogenase, the H_2 -forming methylene- H_4MPT dehydrogenase (Hmd) (96). The methyl group is then transferred to coenzyme M (CoM-SH) by methyl- H_4MPT :CoM methyltransferase (Mtr) in an exergonic reaction that generates an electrochemical sodium ion gradient (9). Methyl-CoM is subsequently reduced to methane by methyl-S-CoM reductase (Mcr) using coenzyme B (CoB-SH), to form a heterodisulfide of coenzyme M and coenzyme B (CoM-S-S-CoB). Finally, H_2 is used to reduce the heterodisulfide via a membrane-bound energy conserving electron transport chain, H_2 :heterodisulfide oxidoreductase system, which is discussed in the next section (reviewed in (21, 22)).

Use of formate as an electron donor involves its initial oxidation to CO_2 and $F_{420}H_2$ by formate dehydrogenase (Fdh). CO_2 enters the hydrogenotrophic pathway and is reduced using four molecules of $F_{420}H_2$ (formed from the oxidation of four formate molecules). Although $F_{420}H_2$ can act as an electron

donor for methenyl and methylene group reduction, it is unclear how it is used to reduce CO_2 and methyl group (23). In *M. maripaludis*, it has been proposed that electrons from F_{420}H_2 are transferred to H_2 by Frh alone or via the concerted action of Mtd and Hmd (Figure 1.3) (67). The H_2 can be subsequently used for reduction steps that cannot utilize F_{420}H_2 .

Figure 1.3 Potential pathways of H_2 production during formate utilization. Initially, Fdh reduces F_{420} . In the first pathway, F_{420}H_2 is oxidized by Frh to produce H_2 . In the second pathway, F_{420}H_2 is oxidized by Mtd to reduce methenyl- H_4MPT to methylene- H_4MPT , which is then reoxidized by Hmd to produce H_2 . Abbreviations are same as in Figure 1.2; HCOO^- , Formate; Fdh, formate dehydrogenase; Hmd, H_2 -forming methylene- H_4MPT dehydrogenase. Figure created from (64).

Similarly, carbon monoxide (CO) can be utilized via the hydrogenotrophic pathway after being oxidized to CO_2 and H_2 by CO dehydrogenase (CODH) in *Methanothermobacter thermoautotrophicus* and *M. barkeri* (64).

1.4.2 Aceticlastic pathway

Acetate catabolism is initiated by its activation to acetyl-CoA (Figure 1.4) (reviewed in (30)). In *Methanosaeta* species, this is accomplished by acetyl-CoA

Figure 1.4 Aceticlastic pathway. Acetate (CH_3COOH) can be split into a methyl group and an enzyme-bound carbonyl moiety. The latter is oxidized to CO_2 to provide electrons required for reduction of the methyl group to methane. Steps not required by this pathway are shaded gray. Abbreviations are same as in Figure 1.2. Figure adapted from (39).

synthetase (ACS) in an AMP and PPi forming reaction. PPi is further cleaved by a pyrophosphatase (5). On the other hand, in *Methanosarcina* species, acetate is initially phosphorylated to acetyl-phosphate by acetate kinase (Ack) at the

expense of one ATP molecule. Phosphotransacetylase (Pta) then exchanges the phosphate group for coenzyme A (5, 50, 66). Acetyl-CoA is subsequently cleaved by the multifunctional enzyme complex, CO dehydrogenase (CODH)/acetyl-CoA synthase (ACDS), into a methyl group that is transferred to H₄MPT and a carboxyl group that is oxidized to CO₂ with concomitant Fd_{red} production (3, 72, 73, 89). The methyl group is reduced to methane as in the hydrogenotrophic pathway, generating CoM-S-S-CoB. Regeneration of free coenzymes from the heterodisulfide occurs via different electron transport systems in *Methanosarcina* species. In *M. barkeri*, H₂ produced from Fd_{red} by the Ech hydrogenase has been proposed to reduce CoM-S-S-CoB via the H₂:heterodisulfide oxidoreductase system (72, 73). However, in *M. acetivorans*, a putative Fd oxidoreductase called Rnf (*Rhodobacter* nitrogen fixation) is responsible for channeling electrons from Fd_{red} to the heterodisulfide via MP (63).

1.4.3 Methylotrophic pathway

The entry of methylated compounds into this pathway (reviewed in (53)) is mediated by substrate-specific methyltransferases (MtaB for methanol) that transfer their methyl groups to a cognate corrinoid protein (MtaC for methanol). Together these two proteins constitute the methyltransferase 1 or MT1. The methyl group is then transferred to CoM-SH by methyltransferase 2 or MT2 (MtaA for methanol) (Figure 1.5). Methyl-CoM is subsequently reduced to methane as in the hydrogenotrophic pathway, generating CoM-S-S-CoB. Electrons needed for the regeneration of free coenzymes from the heterodisulfide

are derived from oxidizing one-fourth of methyl groups attached to CoM-SH to CO₂ via the reverse of the CO₂-reduction pathway. Thus, methyl and methylene

Figure 1.5 Methylotrophic pathway. C1-compounds, such as methanol (CH₃OH), can be disproportionated to CO₂ and methane. In the pathway shown, one molecule of methanol is oxidized to provide electrons for reduction of three additional molecules to methane. Steps not required by this pathway are shaded gray. Abbreviations are same as in Figure 1.2. Figure adapted from (39).

group oxidation produces two molecules of F₄₂₀H₂ (7, 8), whereas, Fd_{red} is generated from formyl group oxidation (72, 73). F₄₂₀H₂ enters the F₄₂₀H₂:heterodisulfide oxidoreductase system for reduction of the heterodisulfide (discussed below, (21, 22)). However, as in the aceticlastic pathway, depending

on the *Methanosarcina* species, reduction of CoM-S-S-CoB by Fd_{red} may involve H₂ (72, 73) as an intermediate or Rnf (63).

1.4.4 Methyl respiration pathway

The methyl groups of methylated compounds (Figure 1.6) enter at the level of methyl-CoM, as in the methylotrophic pathway. However, instead of

Figure 1.6 Methyl respiration pathway. C-1 compounds such as methanol or methylamines can be reduced directly using electrons derived from H₂ oxidation. Steps not required by this pathway are shaded gray. Abbreviations are same as in Figure 1.2. Figure adapted from (39).

being disproportionated into CO₂ and CH₄, they are entirely converted into methane. The heterodisulfide thus generated is reduced using H₂ via the H₂:heterodisulfide oxidoreductase system. Although this pathway was first discovered in *Methanosphaera stadtmaniae* (76), it was later reported in *M. barkeri* as well (39).

1.5 ENERGY CONSERVATION IN *METHANOSARCINA*

All methanogens are obligate methane producers as they conserve energy for growth and survival through methanogenesis. In each methanogenic pathway, formation of methane is accompanied by generation of the CoM-S-S-CoB heterodisulfide, which acts as the terminal electron acceptor in the respiratory chain. Regeneration of free coenzymes from the heterodisulfide is mediated by H₂, F₄₂₀H₂ or Fd_{red} via energy-conserving electron transport chains that have been characterized biochemically in *M. mazei* Gö1 (reviewed in (21, 22, 27-29)). These oxidoreductase systems are described below.

1.5.1 H₂:heterodisulfide oxidoreductase system

In this system, H₂ is used as an electron donor for heterodisulfide reduction (Figure 1.7) (20, 49). The membrane-bound F₄₂₀-nonreducing or methanophenazine-dependent hydrogenase, Vht, oxidizes H₂ in the periplasm to release two protons and two electrons. The electrons are transferred from the bimetallic [NiFe] catalytic center in the large subunit (VhtA), through the [Fe-S] clusters in the small subunit (VhtG), to the cytochrome *b* subunit (VhtC). VhtC

then accepts two protons from the cytoplasm and passes them along with the electrons to the membrane-bound electron carrier, methanophenazine (MP).

Figure 1.7 The electron transport chain of *Methanosarcina* has been proposed to comprise two energy-conserving systems, the H_2 :heterodisulfide oxidoreductase and the $F_{420}H_2$:heterodisulfide oxidoreductase. In the former, H_2 is oxidized by Vht to produce two protons outside the cell and two electrons that are transferred to the membrane-soluble electron carrier MP. Reduction of MP consumes two protons from the cytoplasm, which are subsequently released outside the cell upon oxidation of MPH_2 . The electrons are then transferred through HdrED to reduce CoM-S-S-CoB with two protons from the cytoplasm. Alternatively, in the $F_{420}H_2$:heterodisulfide oxidoreductase, $F_{420}H_2$ is oxidized by FpoF releasing two electrons that are transferred through FpoBCDI and then FpoAHJKLMN to MP. This reaction is coupled to pumping of two protons outside the cell. MPH_2 is then used to reduce CoM-S-S-CoB as in the H_2 :heterodisulfide oxidoreductase. In both systems, the entire electron transport process leads to the net translocation of four protons (highlighted in red) outside the cell per two electrons transferred from $F_{420}H_2$ or H_2 to the CoM-S-S-CoB. Abbreviations are same as in Figure 1.2; FAD, flavin adenine dinucleotide; [FeS], iron-sulfur cluster; [NiFe], bimetallic catalytic center; Cytb, cytochrome *b*; IN, inner face of the cytoplasmic membrane; OUT, outer face of the cytoplasmic membrane. Figure adapted from (56).

Thus, the net reaction leads to production of two scalar protons in the periplasm.

Subsequently, oxidation of reduced MP (MPH_2) by the heterodisulfide reductase

(Hdr) releases two protons in the periplasm and two electrons, which are

transferred through the membrane-integral cytochrome *b* subunit (HdrE) to the

[Fe-S] clusters in the large subunit (HdrD). Finally, HdrD uses these electrons and two protons from the cytoplasm to reduce the CoM-S-S-CoB heterodisulfide. This leads to production of two additional scalar protons in the periplasm. Overall, four protons are translocated per one mole of heterodisulfide reduced. This proton-motive force can then be used for ATP production by the ATP synthase (21, 22).

M. barkeri has been proposed to use this electron transport chain during hydrogenotrophic and methyl-respiration pathways, as these involve use of H₂ as an electron donor (22). In the acetoclastic and methylotrophic pathways, Fd_{red} produced by carbonyl and formyl group oxidation, respectively, is postulated to give rise to H₂ by the action of Ech hydrogenase (72, 73). This H₂ can then be channeled into this oxidoreductase system as well. Although *M. mazei* has been shown to use this energy-conserving system *in vitro* while growing on H₂/CO₂ (49), *M. acetivorans* remains incapable of utilizing it due to its inability to express Vht and lack of the Ech hydrogenase (38, 39) .

1.5.2 F₄₂₀H₂:heterodisulfide oxidoreductase system

This system uses F₄₂₀H₂ to reduce the heterodisulfide (Figure 1.7) (7, 8). The membrane-bound F₄₂₀H₂ dehydrogenase (Fpo) oxidizes F₄₂₀H₂ via its input module (FpoF) to release two electrons that are channeled through FAD and [Fe-S] clusters in FpoF to the membrane-associated module of Fpo (FpoBCDI). Through the [Fe-S] clusters in FpoI and FpoB, the electrons are eventually transferred to the membrane-integral module of Fpo, FpoAHJKLMN, which uses

them to reduce MP. This reaction is coupled to the pumping of two protons outside the cell by Fpo. In addition, MP reduction consumes two protons from the cytoplasm, which are subsequently released in the periplasm on oxidation of MPH₂ by Hdr. This leads to production of two scalar protons in the periplasm. Hdr reduces the CoM-S-S-CoB heterodisulfide as in the H₂:heterodisulfide oxidoreductase system. Overall, this electron transport chain also leads to translocation of four protons outside the cell for one mole of heterodisulfide reduced. This proton-motive force can then be used for ATP production by the ATP synthase (22).

It has been proposed that *M. barkeri*, *M. mazei* and *M. acetivorans* use this electron transport chain during the methylotrophic pathway, in which F₄₂₀H₂ is produced from methyl and methylene group oxidation (22).

1.5.3 Fd_{red}:heterodisulfide oxidoreductase system

In *M. acetivorans*, Fd_{red} produced by the aceticlastic and methylotrophic pathways cannot be converted to H₂ for entry into the H₂:heterodisulfide oxidoreductase system. This is because *M. acetivorans* lacks the Ech hydrogenase and does not express the Vht hydrogenase (38, 39). Based on proteomic (63) and microarray analysis (62), it is postulated that during acetate utilization a membrane-bound complex called Rnf couples Fd_{red} oxidation to heterodisulfide reduction via MP, concomitantly pumping sodium ions outside the cell. The electrochemical sodium gradient can then be exchanged for a proton gradient via a Na⁺/H⁺ antiporter (Mrp) and used to make ATP by the ATP

synthase (31). Rnf and Mrp are absent in *M. barkeri* and *M. mazei* (26, 69). It is not known if Rnf or some other redox enzyme is responsible for Fd_{red} oxidation in the methylotrophic pathway. A putative Fd oxidoreductase capable of transferring electrons from Fd_{red} to CoM-S-S-CoB in a H_2 -independent way has also been proposed in *M. barkeri* methylotrophic pathway. However, the identity of this protein is not known (73).

1.5.4 Mtr-catalyzed methyl group transfer from methyl- H_4MPT to CoM-SH

Mtr is a membrane-bound, eight-subunit enzyme that is encoded by the *mtrECDBAFGH* operon (Figure 1.8) (36). In the hydrogenotrophic and acetoclastic pathways, it catalyzes the exergonic transfer of methyl group from $\text{CH}_3\text{-H}_4\text{MPT}$ to CoM-SH, concomitantly pumping two sodium ions outside the cell and conserving energy (9). On the other hand, during methanol utilization, Mtr catalyzes the reverse reaction (methyl transfer from $\text{CH}_3\text{-CoM}$ to H_4MPT) by coupling it to the consumption of the sodium ion gradient (34, 41). The requirement of sodium ions by Mtr renders growth of methanogens Na^+ ion-dependent (36).

1.5.5 Ech-catalyzed H_2 production from Fd_{red}

Ech is a membrane-bound [NiFe] hydrogenase (Figure 1.8, described below in detail). In the hydrogenotrophic pathway, it couples the endergonic transfer of electrons from H_2 to Fd_{ox} with the consumption of an electrochemical proton gradient (72, 73). It has been postulated that this proton gradient is

created using the sodium ion gradient that is generated by the Mtr reaction in this pathway (51, 52, 106). This inter-conversion of ion gradients may be mediated by

Figure 1.8 Ion-translocating protein complexes in *Methanosarcina*. Ech hydrogenase: H₂ is oxidized on the inner side of the membrane by EchE. The electrons thus released are passed through EchC and EchF to Fd_{ox}. This endergonic reaction is coupled to the import of an unknown number of protons inside the cell (42, 58, 72). **Methyl-H₄MPT:CoM methyltransferase (Mtr):** The transfer of the methyl group from H₄MPT to CoM-SH involves a corrinoid group (CO) attached to the MtrA subunit. Initially, MtrH subunit catalyzes the methylation of the MtrA protein with methyl-H₄MPT. MtrE subunit then catalyzes the transfer of the methyl group from MtrA to CoM-SH, resulting in translocation of two sodium ions outside the cell (9, 36). **Na⁺/H⁺ antiporter** exchanges sodium ions for protons (106). **ATP synthase** couples import of protons into the cell with ATP synthesis (78). Abbreviations are same as in Figures 1.2 and 1.7.

the Na⁺/H⁺ antiporter, which is found in methanogens (Figure 1.8) (63, 79, 111).

By analogy to its *Escherichia coli* homolog, the H⁺/Na⁺ stoichiometry of this antiporter is probably two (85, 102, 106). In the aceticlastic and methylotrophic pathways, Ech presumably catalyzes the exergonic production of H₂ from Fd_{red}, concomitantly pumping protons outside the cell (72, 73). Once converted into a sodium ion gradient, this proton gradient may be used to drive the endergonic

Mtr reaction in the methylotrophic pathway. It should be noted that *M. acetivorans* that lacks Ech cannot carry out these H₂-dependent reactions (38, 39).

1.5.6 A₁A₀ ATPase

As outlined above, methanogenesis is coupled to the generation of electrochemical proton and sodium ion gradients that can be used to synthesize ATP using an ATPase (Figure 1.8). Archaea contain a unique class of ATPases, the A₁A₀ ATPases that are structurally similar to eukaryal V₁V₀ ATPases, but function as ATP synthases like the bacterial F₁F₀ ATPases (78). The coupling ion for the ATPase is H⁺ (87), however, the H⁺ to ATP stoichiometry is uncertain, but is presumed to be 4 for most methanogens (80, 106). The genes encoding the ATPase from *M. mazei* Gö1 constitute one operon, *ahaHIKECFABD*, which is also present in the genomes of *M. barkeri* Fusaro and *M. acetivorans* C2A (80). Interestingly, the latter two species also contain a F₁F₀ ATPase, but its functionality is not yet known (78).

1.6 ENERGY CONSERVATION IN OTHER METHANOGENS

Apart from members of the order *Methanosarcinales*, all methanogens are devoid of MP and cytochromes. In addition, they lack the membrane-bound Vht and HdrED enzymes. Therefore, these hydrogenotrophic methanogens cannot conserve energy via the H₂:heterodisulfide oxidoreductase system described above. Instead, they employ a cytoplasmic multi-enzyme complex that is

composed of [NiFe] hydrogenase MvhADG and heterodisulfide reductase (HdrABC) (Figure 1.9). This complex has been proposed to couple the exergonic reduction of heterodisulfide with H_2 to the endergonic reduction of Fd_{ox} , also by

Figure 1.9 Proposed scheme for the reduction of CoM-S-S-CoB with H_2 that is catalyzed by the hydrogenase (MvhADG)-heterodisulfide reductase (HdrABC) complex in methanogens without cytochromes. The enzyme complex is proposed to couple the endergonic reduction of Fd_{ox} with H_2 to the exergonic reduction of CoM-S-S-CoB with H_2 by flavin-based electron dismutation that involves the FAD in HdrA. Abbreviations are same as in Figures 1.2 and 1.7. Figure created from (106).

H_2 (106). The reaction proceeds via a flavin-based electron bifurcation mechanism that is similar to the one recently characterized during butyrate fermentation in *Clostridium kluyveri* (61). Thus, the Mvh hydrogenase oxidizes two molecules of H_2 to release electrons for reduction of the heterodisulfide at HdrC and Fd_{ox} at FAD-containing HdrA. The Fd_{red} can then be used for reduction of CO_2 to the formyl level in the first step of hydrogenotrophic methanogenesis. As aforementioned, *Methanosphaera stadtmanae* can only reduce methanol to methane. Hence, it utilizes the Fd_{red} generated by the Mvh-Hdr complex for H_2

production using an Ech-like hydrogenase called Ehb, which couples this reaction to the build-up of an ion-motive force. This electrochemical gradient can be subsequently used for ATP synthesis by the ATP synthase (106).

1.7 COMPONENTS OF ELECTRON TRANSPORT SYSTEMS IN METHANOSARCINA

The electron transport systems involve various redox enzymes that shuttle electrons between the four major electron carriers: H₂, F₄₂₀, Fd and MP. These enzymes include hydrogenases, Fpo and Hdr.

1.7.1 Ech: Fd_{ox}-dependent hydrogenase

Ech (*E. coli* c [for three] hydrogenase (58) or Energy converting hydrogenase (42)) is a multi-subunit membrane-bound [NiFe] hydrogenase that catalyzes the reversible reduction of Fd_{ox} with H₂ (Figure 1.8) (72). It belongs to a family of hydrogenases that are closely related to the proton-pumping NADH:quinone oxidoreductase (Nuo, complex I of *E. coli*). This family also includes *E. coli* hydrogenases 3 and 4, CO-induced hydrogenase from *Rhodospirillum rubrum* and Eha and Ehb from *Methanothermobacter* species (42).

Ech purified from *M. barkeri* (72) is composed of six subunits that are encoded by the *echABCDEF* operon (73). EchE and EchC are the large and small subunits of [NiFe] hydrogenases, respectively. Thus, EchE harbors the bimetallic [NiFe] catalytic center and EchC a [4Fe-4S] cluster. In addition to these subunits, EchF and EchD are also hydrophilic. Although the function of EchD is

unknown, EchF is an electron transfer protein containing two [4Fe-4S] clusters (58). The rest of the subunits, EchA and EchB, are membrane-bound and show homology to the proton-pumping subunits of Nuo (Nuo H and NuoL, respectively). Therefore, they may be involved in ion translocation during Ech activity (42, 58). It has been proposed that electrons released from H₂ oxidation at EchE are channeled through the [Fe-S] clusters in EchC and EchF to Fd_{ox} (72).

In *M. barkeri*, a soluble 2[4Fe-4S] Fd_{ox} ($E^{\circ} = -420$ mV) is the physiological electron acceptor of Ech. Reduction of this Fd_{ox} by H₂ ($E^{\circ} = -414$ mV) is endergonic, especially in methanogenic habitats with low H₂ partial pressure ($E' = -286$ mV at 5 Pa). There is evidence to suggest that Ech drives this unfavorable reaction by coupling it to the consumption of a proton gradient called reverse electron transport. The Fd_{red} thus generated is used to reduce CO₂ to the formyl level in the first step of hydrogenotrophic methanogenesis (Figure 1.2). Also, it is needed for biosynthesis of acetyl-CoA and pyruvate via the ACDS (Reaction 1) and pyruvate:ferredoxin oxidoreductase (POR, reaction 2) catalyzed reactions, in the hydrogenotrophic and methyl-respiration pathways. During acetate utilization, oxidation of carbonyl group to CO₂ produces Fd_{red} (Figure 1.4). Ech renders this reaction energy-conserving by coupling H₂ formation from Fd_{red} to generation of a proton-motive force. Subsequently, the H₂ presumably enters the H₂:heterodisulfide oxidoreductase system for reduction of the heterodisulfide (Figure 1.7). A similar role of Ech has also been proposed in the methylotrophic pathway, in which Fd_{red} produced by formyl group oxidation may be converted

into H₂ by Ech (Figure 1.5). However, mutational analysis of *ech* revealed that electrons from Fd_{red} can be transferred to the heterodisulfide in an Ech- or H₂-independent manner (72, 73).

Consistent with its role in each methanogenic pathway, *ech* is expressed on all substrates tested in *M. barkeri*. Notably, *ech* expression on acetate is ca. ten-fold more than on other substrates (38, 58). The *echABCDEF* operon is found in *M. barkeri* (69) and *M. mazei* (22), but is absent in *M. acetivorans* (33). Other hydrogenotrophic methanogens like *M. marburgensis* (103) and *M. maripaludis* (88) contain two Ech-like hydrogenases, Eha and Ehb. Although these belong to the same family as Ech, their subunit composition is different from Ech.

1.7.2 Frh: F₄₂₀-reducing hydrogenase

Frh (F₄₂₀-reducing hydrogenase) is a soluble [NiFe] flavoprotein that catalyzes the reversible reduction of coenzyme F₄₂₀ with H₂ (Figure 1.10) (74). F₄₂₀ (E° = -360 mV) is a deazaflavine derivative that carries hydride ions and is responsible for the characteristic blue auto-fluorescence of methanogens (23). Frh purified from *M. barkeri* is a three-subunit enzyme, encoded by the *frhADGB* operon (74, 110). FrhA is the large subunit of [NiFe] hydrogenases that harbors

the [NiFe] catalytic center, whereas FrhG is the small subunit containing at least 2 [4Fe-4S] clusters. FrhB is a flavoprotein that binds F_{420} and FrhD is a putative maturation peptidase needed for FrhA processing (6, 38, 74). A plausible route

Figure 1.10 F_{420} -reducing hydrogenase. Frh catalyzes the reversible oxidation of $F_{420}H_2$ with H_2 in the cytoplasm (74). Abbreviations are same as in Figures 1.2 and 1.7.

for electron transfer to F_{420} involves oxidation of H_2 at the [NiFe] center in FrhA to release electrons that are channeled through the [Fe-S] clusters in FrhG to FAD in FrhB. Finally, FAD donates electrons to F_{420} via the $1e^-/2e^-$ redox switch (6).

$F_{420}H_2$ serves as an electron donor for reduction of methenyl and methylene groups in the hydrogenotrophic pathway (Figure 1.2) (6, 74, 104). This is consistent with *frh* expression on H_2/CO_2 in *M. barkeri*. However, it is unclear why *frh* is also expressed on methanol. On the other two substrates, methanol plus H_2/CO_2 and acetate, *frh* expression is down-regulated two to three-fold (38).

While *M. barkeri*, *M. mazei* and *M. acetivorans* each possess the *frhADGB* operon, *M. barkeri* also contains a second *freAEGB* operon that lacks the gene *D* (38, 110). Moreover, subunit E does not show homology to subunit D or any other protein in the database. The *fre* operon encodes a hydrogenase that is 85-

87% identical to Frh (110). In addition, Fre contains all the important structural and catalytic residues that are present in Frh. Thus, it has been proposed that Fre might be functional if it undergoes processing by FrhD. In *M. barkeri*, *fre* is expressed at very low levels on all methanogenic substrates. The expression of *frh* is undetectable in *M. acetivorans* under all tested conditions (38).

Some methanogens like *Methanococcus voltae* (40), *Methanococcus jannaschii* (15) and *M. maripaludis* (45), contain two isozymes of F₄₂₀-reducing hydrogenases. In one of these, an active-site cysteine residue is replaced by selenocysteine. The non-selenium containing hydrogenases are only synthesized in the absence of selenium in *M. voltae* (100).

1.7.3 Vht: F₄₂₀-nonreducing or MP-dependent hydrogenase

Vht (**Viologen hydrogenase two**) is a membrane-bound [NiFe] hydrogenase that catalyzes the reversible reduction of MP (Figure 1.7) ($E^{\circ} = -165$ mV (108)) with H₂ (10, 24). Although Vht was purified from both *M. mazei* Gö1 (25) and *M. barkeri* MS (54), characterization of the enzyme was done using the *M. mazei* enzyme preparation. This preparation was found to contain two isozymes called Vho (**Viologen hydrogenase one**) and Vht (**Viologen hydrogenase two**) that are ca. 95% identical and are encoded by the *rhoGAC* and *vhtGACD* operons, respectively (19, 24). The A subunit is the hydrogenase large subunit with the [NiFe] catalytic center, whereas the G subunit is the small subunit containing [Fe-S] clusters and a Tat signal peptide, which probably localizes the enzyme to the periplasmic side of the membrane. Subunit C is a

cytochrome *b* and the D subunit, which is absent in *vho*, is a putative hydrogenase maturation protease needed for processing of the large hydrogenase subunit (24, 38). It has been proposed that electrons released from H₂ oxidation at Vht/VhoA are channeled through the [Fe-S] clusters in Vht/VhoG to Vht/VhoC, which then passes them on to MP (22). Washed membrane vesicles containing Vht/Vho and Hdr have been shown to catalyze H₂-dependent reduction of the CoM-S-S-CoB heterodisulfide, in the presence of 2-hydroxyphenazine (a soluble analog of MP). This reaction is coupled to the generation of a proton gradient (4H⁺/2e⁻), which is used to drive ATP synthesis (20, 49). Both Vho/Vht and Hdr can also function with chemically synthesized MP (10).

Thus, Vht channels electrons from H₂ oxidation to MP, which is then used as an electron donor by Hdr for heterodisulfide reduction in the terminal step of methanogenesis (49). The source of H₂ in the hydrogenotrophic pathway (Figure 1.2) is external (22, 104), whereas in the acetoclastic (Figure 1.4) and methylotrophic (Figure 1.5) pathways, H₂ is presumably produced from Fd_{red} by the Ech hydrogenase (72, 73).

In addition to *vho* and *vht*, *M. mazei* genome (26) harbors a third operon (*vhxGAC*) that encodes the methanophenazine-dependent hydrogenase Vhx (Vho-like hydrogenase with unknown [x] function) (38). Phylogenetic analysis indicates that Vho and Vht group together to the exclusion of Vhx (ca. 50% amino acid identity to the other two hydrogenases). Thus, *vho* could have arisen from a recent duplication in *M. mazei* genome (38). Both *M. barkeri* (69) and *M.*

acetivorans (33) possess one operon that is similar to *vhoGAC/vhtGACD* (designated as *vhtGACD*) and another to *vhxGAC*. The presence of *vhx* in all *Methanosarcina* species suggests that it was in their genomes before they diverged from each other. The deduced sequences of Vht/Vhx enzymes from *M. barkeri* and *M. acetivorans* possess all the important structural and catalytic residues that are present in *M. mazei* hydrogenases. However, the only exception is the VhxG subunits from *M. barkeri* and *M. mazei* that lack the first conserved cysteine residue in the motif CXXCXnGXCXXXGXmGCP, which is characteristic of the small hydrogenase subunits. Like *vho*, *vhx* lacks the maturation protease-encoding gene *D*. As methanophenazine-dependent hydrogenases are presumed to undergo post-translational modification using subunit D, it has been proposed that *vhtD* may provide this protease in *trans* for processing of Vho and Vhx enzymes (38).

The reason(s) for the existence of multiple methanophenazine-dependent hydrogenases in *Methanosarcina* species is unclear. A plausible explanation could be differential regulation of expression, as seen in *M. mazei*, in which *vho* is expressed constitutively on methanol, trimethylamine, H₂/CO₂ and acetate, whereas *vht* is not expressed on acetate (19). In *M. barkeri*, *vhx* is not expressed at detectable levels on any methanogenic substrate tested, whereas expression of *vht* is constitutive. Like *frh*, *vht* is also not expressed in *M. acetivorans*. However, *vhx* is expressed at very low levels on H₂/CO₂, methanol and methanol plus H₂/CO₂ and is up-regulated five-fold on acetate (38).

The F₄₂₀-nonreducing hydrogenases from other methanogens is cytoplasmic, lacks cytochrome and does not interact with MP (106). Therefore, it should be considered as distinct from Vht, despite their common name. For instance, the enzyme from *M. marburgensis* (95, 101) is composed of three subunits, MvhDGA, out of which MvhA and MvhG are the large and small subunits of [NiFe] hydrogenases, respectively. The MvhD subunit has been proposed to interact with Hdr and provide electrons for heterodisulfide reduction. Another subunit encoded by the *mvhDGAB* operon (MvhB) is a polyferredoxin with an unknown function. Similar enzymes are found in *M. jannaschii* (15), *M. kandleri* (99), *M. maripaludis* (45) and *M. voltae* (40). The latter two species contain two isozymes of F₄₂₀-nonreducing hydrogenases, a [NiFe] Vhc and another [NiFeSe] Vhu, encoded by *vhcDGAB* and *vhuDGAUB* operons, respectively.

1.7.4 Hyp: Hydrogenase maturation proteins

The synthesis and insertion of metal center in [NiFe] hydrogenases requires auxiliary proteins called Hyp, which have been well characterized in *E. coli*. The postulated pathway of maturation of hydrogenase 3 from *E. coli* involves six Hyp proteins that are encoded by the *hypABCDE* operon and *hypF* (Figure 1.11) (13). Firstly, the HypC and HypD proteins form a complex that binds an Fe atom. HypE and HypF then synthesize the CO and CN ligands of Fe atom from carbamoyl phosphate in an ATP-dependent reaction. HypD, which is an iron-sulfur protein, may provide electrons for attachment of these ligands to

the Fe atom (12, 13). Subsequently, HypC dissociates from HypD and binds the unmetallated large hydrogenase subunit (Pre-HycE) via one of its Ni-binding cysteine ligands (70). This helps maintain the protein in a conformation that is

Figure 1.11 Postulated pathway of the maturation of hydrogenase 3 from *E. coli* (HycE).

HypC and HypD form a complex with the Fe atom, which gets liganded to CO and CN groups that are synthesized from CP by HypE and HypF. HypC then dissociates from HypD and inserts the Fe atom into the precursor of HycE (pre-HycE). HypA and HypB subsequently catalyze coordination of the Ni atom into pre-HycE. HypC dissociates from the metallated pre-HycE, which is then acted upon by an endopeptidase that cleaves a carboxyl terminal peptide. This is followed by bridging of the two atoms via cysteine groups and closing of the metal center. Abbreviations, CP: carbamoyl phosphate; CO: carbon monoxide; CN: cyanide. Figure adapted from (12, 13).

accessible for metal insertion. Thus HypC acts as a chaperone. It then inserts the liganded Fe atom into the active site. This is followed by coordination of Ni atom into the large subunit precursor by HypA and HypB (GTPase), in concomitance with GTP hydrolysis (12, 13). Once HypC dissociates from the metallated

subunit, the Ni atom acts as a recognition signal for an endopeptidase that is encoded *in cis* with the hydrogenase. It cleaves an oligopeptide from the C-terminus leading to a conformational change that allows bridging of the Ni and Fe atoms through cysteine residues. This closes the metal center of the large subunit and enables its interaction with the small subunit (13, 107).

All three *Methanosarcina* species (26, 33, 69) possess a *hypCDABE* operon and *hypF*. In addition, *M. mazei* has extra copies of *hypB* and *hypC*. These proteins presumably carry out the same reactions during maturation of Ech, Frh, Fre, Vho, Vht and Vhx hydrogenases. However, Ech may not undergo the terminal processing step involving the endopeptidase, as it lacks the carboxyl terminal oligopeptide (58).

1.7.5 Hmd: Iron-sulfur cluster-free hydrogenase

In addition to Fd-, F₄₂₀⁻ and F₄₂₀-non reducing hydrogenases, members of *Methanobacteriales*, *Methanococcales* and *Methanopyrales* (35) also contain an iron-sulfur cluster-free hydrogenase that is phylogenetically unrelated to [FeFe] and [NiFe] hydrogenases (96). As mentioned above, this hydrogenase called H₂-forming methylene-H₄MPT dehydrogenase (Hmd) catalyzes the reversible reduction of methenyl-H₄MPT to methylene-H₄MPT with H₂ in the hydrogenotrophic pathway. Since this reaction can also be catalyzed by the concerted action of [NiFe] hydrogenase Frh and Mtd, Hmd is only essential under Ni-limiting conditions. Under such conditions, Hmd, in conjunction with Mtd, is also used for synthesis of F₄₂₀H₂ (Figure 1.3) (96). Together Hmd and Mtd also

catalyze the reverse reaction leading to H₂ production from F₄₂₀H₂ during formate utilization (46, 67).

The Hmd holoenzyme comprises of a homodimer, two pyridone derivative cofactor molecules and two Fe atoms (35). The protein is encoded by the *hmd* gene. Interestingly, methanogens with *hmd* also contain one or two *hmd* homologs that encode for proteins that are only *ca.* 20% identical to Hmd. The role of these proteins seems to be Hmd-related but is still unclear (96).

1.7.6 Fpo: F₄₂₀H₂ dehydrogenase

Fpo (F₄₂₀H₂ phenazine oxidoreductase) is a membrane-bound F₄₂₀H₂ dehydrogenase that catalyzes the transfer of electrons from F₄₂₀H₂ to MP, concomitantly pumping two protons outside the cell (Figure 1.7) (7). It was first purified from *M. mazei* Gö1 as a five-subunit complex (FpoBCDIF) capable of oxidizing F₄₂₀H₂ with a variety of artificial electron acceptors (4). Searching the genome for N-terminal amino acid sequences of these proteins resulted in the discovery of a 13-gene operon, *fpoABCDHIJJKLMNO* (*fpo*), containing *fpoBCDI*, with *fpoF* being located elsewhere on the genome (7). Fpo shares significant homology with NADH:quinone oxidoreductase (Nuo) of *E. coli* and the nomenclature reflects that similarity. Accordingly, both Fpo and Nuo are composed of similar membrane-integral (the A, H, J, K, L, M and N subunits) and membrane-associated (the B, C, D and I subunits) modules. However, the enzymes differ in their substrates and hence in their input modules, such that NuoEFG oxidizes NADH, whereas FpoF oxidizes F₄₂₀H₂. Another difference

between the enzymes is the presence of an additional hydrophilic iron-sulfur subunit of unknown function in Fpo, FpoO, which has no homolog in Nuo. Notably, the FpoF subunit shares homology with FrhB subunit of F₄₂₀-reducing hydrogenases (7, 21, 22).

It is postulated that electrons released from F₄₂₀H₂ oxidation at FpoF are channeled through the enzyme-bound FAD and [Fe-S] cluster to the [Fe-S] clusters in FpoI and FpoB. Subsequently, they are transferred via the membrane-bound module FpoAHJKLMN, which is predicted to be involved in proton extrusion, to MP (7, 21, 22). Washed membrane vesicles containing Fpo and Hdr have been shown to catalyze F₄₂₀H₂-dependent reduction of the CoM-S-S-CoB heterodisulfide, in the presence of 2-hydroxyphenazine. This reaction is coupled to the generation of a proton gradient (4H⁺/2e⁻), which is used to drive ATP synthesis (7, 8). Both Fpo and Hdr can also function with chemically synthesized MP (10).

Thus, Fpo couples oxidation of F₄₂₀H₂, generated during the methylotrophic pathway (Figure 1.5), to MP reduction and pumping of two protons outside the cell. MPH₂ is then used for reduction of the heterodisulfide by Hdr (7).

M. barkeri (69) and *M. acetivorans* (33) also contain the *fpo* operon and *fpoF*. Interestingly, when grown on CO as the growth substrate, *M. acetivorans* Fpo has been proposed to contain a small additional subunit, FpoP. However, there is no experimental evidence that FpoP protein is produced, nor is the gene

conserved in the other two *Methanosarcina* species. Thus it is still unknown if FpoP has a role in methanogenesis from any substrate (60).

1.7.7 Hdr: Heterodisulfide reductase

Hdr is a membrane-bound iron-sulfur hemoprotein that catalyzes the reversible reduction of the heterodisulfide of coenzyme M and coenzyme B, CoM-S-S-CoB ($E^{\circ'} = -143$ mV (108)), with MPH_2 (Figure 1.7) (10, 57). Hdr purified from *M. barkeri* (44) is a two-subunit enzyme encoded by the *hdrED* operon. HdrE represents a membrane-integral cytochrome *b*, whereas HdrD is a hydrophilic subunit containing two [4Fe-4S] clusters (57). Electrons produced from the oxidation of MPH_2 are presumably transferred to cytochrome *b* and the protons are released at the outer phase of the cytoplasmic membrane. Subsequently, the electrons are channeled through the [4Fe-4S] clusters of HdrD to the heterodisulfide, which gets reduced by consumption of two protons from the cytoplasm (22). The scalar production of protons by HdrED has been demonstrated in washed membrane vesicles of *M. mazei* Gö1. This experimental system was also used to validate HdrED as a part of the H_2 :heterodisulfide and F_{420}H_2 :heterodisulfide oxidoreductase systems (7, 8, 20, 49).

As the CoM-S-S-CoB heterodisulfide is generated in all aforementioned methanogenic pathways, HdrED plays a key role in energy conservation in methanogenesis. Depending on the substrate utilized, it reduces the heterodisulfide using electrons from the oxidation of H_2 , F_{420}H_2 or Fd_{red} via MP (21, 22).

All methanogens, except members of the order *Methanosarcinales*, lack the membrane-bound, cytochrome-containing Hdr (106). Instead, they possess a soluble Hdr that is composed of three different subunits, HdrABC (Figure 1.9) (reviewed in (43)). This enzyme has been purified and characterized from *M. marburgensis*. HdrA is a flavoprotein with four [4Fe-4S] clusters, whereas HdrC contains two [4Fe-4S] clusters. Although HdrB contains no characteristic cofactor-binding motif, it is probably the site of heterodisulfide reduction. Based on sequence similarity, HdrE is presumed to be a fusion protein of HdrB and HdrC subunits.

In addition to HdrED, these hydrogenotrophic methanogens also lack cytochromes, MP and a membrane-bound F_{420} -nonreducing hydrogenase (106). Thus, energy conservation using the cytoplasmic HdrABC enzyme is unclear. However, a recent review by Thauer *et al* (106) proposes that a soluble complex of the F_{420} -nonreducing hydrogenase (MvhDGA) and HdrABC, couples reduction of heterodisulfide to Fd_{ox} reduction with H_2 , using a flavin-based bifurcation mechanism. The Fd_{red} is then used to catalyze the reduction of CO_2 to the formyl group in the first step of hydrogenotrophic methanogenesis.

Surprisingly, all sequenced *Methanosarcinales* genomes contain homologs of the *hdrABC* genes, in addition to *hdrED* (26, 33, 69). However, their function in methanogenesis in these organisms is unknown.

1.8 OUTLINE OF WORK PRESENTED IN THE THESIS

The energy-conserving electron transport chains of *Methanosarcina* have been modeled on the basis of *in vitro* biochemical studies (7, 20, 49). In this work, I employed a variety of genetic techniques that have been developed in the Metcalf lab (90) to investigate the *in vivo* roles of various components of these electron transfer systems. In Chapter 2, deletion analysis of the $F_{420}H_2$ -metabolizing enzymes: Fpo, Frh and Fre (7, 110) revealed that *M. barkeri* uses a branched electron transport chain to conserve energy during methylotrophic growth. Thus, only a fraction of $F_{420}H_2$ generated during methyl group oxidation enters into the $F_{420}H_2$:heterodisulfide oxidoreductase system (7). Most of the $F_{420}H_2$, however, is oxidized by Frh to produce H_2 , which is probably channeled into the H_2 :heterodisulfide oxidoreductase system via Vht or Vhx (38, 49). In Chapter 3, deletion analysis of Vht and Vhx confirmed H_2 as a bona fide intermediate in the methylotrophic pathway, hence supporting “ H_2 -cycling” (83) as a mechanism of energy conservation in *M. barkeri* methylotrophic pathway. In this mechanism, H_2 produced from $F_{420}H_2$ oxidation by Frh in the cytoplasm diffuses out of the cell to the active site of Vht in the periplasm. Vht then oxidizes H_2 to regenerate protons, thus leading to the establishment of a trans-membrane proton gradient, which can be used for ATP synthesis by the ATP synthase. Due to the pivotal roles displayed by hydrogenases in *M. barkeri*, I characterized them further in Chapter 4. This was accomplished by constructing a series of single, double, triple, quadruple and quintuple hydrogenase gene deletion mutants. These mutants were then characterized in terms of growth, methane and CO_2

production, hydrogenase activity and expression of various genes. This analysis would also give us insight into the H₂-independent electron-transport chains of *M. barkeri*. In conclusion, the work presented here enhanced our understanding of energy conservation pathways in *Methanosarcina* species. Moreover, this knowledge could be possibly extrapolated to other anaerobic organisms, which possess hydrogenases and are hypothesized to utilize them during energy conservation (18, 82, 84).

CHAPTER 2

HYDROGEN IS A PREFERRED INTERMEDIATE IN THE ENERGY CONSERVING ELECTRON TRANSPORT CHAIN OF *METHANOSARCINA BARKERI*

2.1 ABSTRACT

Methanogens utilize an unusual energy-conserving electron transport chain that involves reduction of a limited number of electron acceptors to methane (CH₄) gas. Previous biochemical studies suggested that the proton pumping F₄₂₀H₂ dehydrogenase (Fpo) plays a crucial role in this process during growth on methanol. However, *Methanosarcina barkeri* Δfpo mutants investigated in this study display no measurable phenotype on this substrate, indicating that Fpo plays a minor role, if any. In contrast, Δfrh mutants lacking the cytoplasmic F₄₂₀-reducing hydrogenase (Frh) are severely affected in their ability to grow and make methane from methanol, while double $\Delta fpo \Delta frh$ mutants are completely unable to utilize this substrate. These data suggest that the preferred electron transport chain involves production of H₂ in the cytoplasm, which then diffuses out of the cell where it is reoxidized with transfer of electrons into the energy conserving electron transport chain. This “hydrogen cycling” metabolism leads directly to production of a proton motive force that can be used by the cell for ATP synthesis. Nevertheless, *M. barkeri* does have the flexibility to utilize the Fpo-dependent electron transport chain when needed, as shown by the poor growth of the Δfrh mutant. Our data support a model in which the rapid enzymatic turnover of hydrogenases may allow a competitive advantage via faster growth rates in this freshwater organism. The mutant analysis also confirms the

proposed role of Frh in growth on hydrogen (H₂)/carbon dioxide (CO₂) and suggests that either Frh or Fpo is needed for acetoclastic growth of *M. barkeri*.

2.2 INTRODUCTION

Methanogenesis is the terminal step in biomass degradation in many anaerobic environments and plays a central role in the global carbon cycle. Although most of the CH₄ produced is oxidized to CO₂ by methane consuming organisms, substantial quantities (ca. 10¹⁴ g/year) escape into the atmosphere where it acts as a potent greenhouse gas (49). Most methanogens produce CH₄ by reducing CO₂ with H₂ (11). However, some *Methanosarcina* species like *M. barkeri* and *M. mazei* are also capable of utilizing a variety of other substrates, including acetate, which accounts for ca. two-thirds of global CH₄ production (16), and C-1 compounds like methanol, methylsulfides and methylamines (10). Four distinct, but overlapping, methanogenic pathways are involved in the use of these diverse substrates (Figure 2.1).

Methanogenic organisms produce CH₄ as a byproduct of anaerobic respiration involving a unique energy-conserving electron transport chain found only in Archaea. At least two distinct types of methanogenic respiration exist: one found in methanogens, including *Methanosarcina* species, that synthesize cytochromes and the other in those that lack cytochromes (49). The penultimate step of both respiratory pathways involves the reduction of methyl-Coenzyme M (CoM-SH, mercaptoethanesulfonic acid) to CH₄ using coenzyme B (CoB-SH, *N*-7-mercaptoheptanoyl-O-phospho-L-threonine) as the electron donor. The other

product of this reaction is the heterodisulfide of CoM-SH and CoB-SH (CoM-S-S-CoB), which serves as the terminal electron acceptor in the energy-conserving

Figure 2.1 Four overlapping methanogenic pathways found in *Methanosarcina barkeri* (adapted from (19)). Each pathway shares a common step in the reduction of methyl-CoM to methane; however, they differ in the route used to form methyl-CoM and in the source of electrons used for its reduction to methane. Many methanogens reduce CO_2 to methane using electrons derived from the oxidation of H_2 (hydrogenotrophic pathway, A) Alternatively, acetate can be split into a methyl group and an enzyme-bound carbonyl moiety. The latter is oxidized to CO_2 to provide electrons required for reduction of methyl group to methane (aceticlastic pathway, B) C-1 compounds like methanol or methylamines can be disproportionated to CO_2 and methane via the methylotrophic pathway, C) In this pathway, one molecule of the C-1 compound is oxidized to provide electrons for reduction of three additional molecules to methane. Finally, C-1 compounds can also be reduced using electrons derived from H_2 oxidation (methyl respiration

Figure 2.1 (cont.)

pathway, D) Steps not required by each pathway are shown in gray. The steps catalyzed by Fpo, Frh, Vht/Vhx, Ech and Hdr proteins are indicated: note that Fpo is predicted to be required in the methylotrophic pathway and Frh in the hydrogenotrophic pathway. Abbreviations; Ech, Fd_{ox}-dependent hydrogenase; Frh, F₄₂₀-reducing hydrogenase; Fpo, F₄₂₀H₂:phenazine oxidoreductase; Vht/Vhx, methanophenazine-dependent hydrogenase; Hdr, heterodisulfide reductase; CoM-SH, coenzyme M; CoB-SH, coenzyme B; CoM-S-S-CoB, mixed disulfide of CoM-SH and CoB-SH; MP/MPH₂, oxidized and reduced methanophenazine; F₄₂₀/F₄₂₀H₂, oxidized and reduced Factor 420; Fd_{ox}/Fd_{red}, oxidized and reduced ferredoxin; CHO-MF, formyl-methanofuran; CHO-H₄SPT, formyl-tetrahydrosarcinapterin; CH≡H₄SPT, methenyl-tetrahydrosarcinapterin; CH=H₄SPT, methylene-tetrahydrosarcinapterin; CH₃-H₄SPT, methyl-tetrahydrosarcinapterin; CH₃-CoM, methyl-coenzyme M.

electron transport chain. In methanogenic archaea that lack cytochromes, the means by which energy is conserved is poorly understood, but probably involves a cytoplasmic electron bifurcation pathway similar to one recently characterized in *Clostridium* (25, 49). In contrast, the energy-conserving electron transport chain of cytochrome-containing methanogens, exemplified by *Methanosarcina* species, has been studied in detail, including the reconstitution of two distinct proton-translocating electron transport systems *in vitro* (4, 5, 12, 22).

In *Methanosarcina* species, a membrane-bound electron transport chain that terminates with the reduction of the CoM-S-S-CoB heterodisulfide generates ion-motive force that can be used by ATP synthase to form ATP (Figure 2.2). Either H₂ or reduced coenzyme F₄₂₀ (F₄₂₀H₂) can donate electrons for reduction of CoM-S-S-CoB (10, 11). In the H₂:heterodisulfide oxidoreductase system, a methanophenazine-dependent hydrogenase (Vht or Vhx (18)) oxidizes H₂ in the periplasm with transfer of two electrons to the membrane soluble electron carrier methanophenazine (MP). The reduced MP (MPH₂) is subsequently oxidized by the enzyme heterodisulfide reductase (Hdr) with concomitant reduction of CoM-S-S-CoB. In the F₄₂₀H₂:heterodisulfide oxidoreductase system, the F₄₂₀H₂

dehydrogenase (Fpo) catalyzes electron transfer from $F_{420}H_2$ to MP, concomitantly pumping two protons out of the cell. As in the H_2 :heterodisulfide

Figure 2.2 The electron transport chain of *M. barkeri* has been proposed to comprise two energy-conserving systems, the $F_{420}H_2$:heterodisulfide oxidoreductase and the H_2 :heterodisulfide oxidoreductase. In the former, $F_{420}H_2$ is oxidized by FpoF releasing two electrons that are transferred through FpoBCDI and then FpoAHJKLMN to membrane-soluble MP. This reaction is coupled to pumping of two protons outside the cell. Reduction of MP consumes two protons from the cytoplasm, which are subsequently released outside the cell upon oxidation of MPH_2 . The electrons are then transferred through HdrED to reduce CoM-S-S-CoB with two protons from the cytoplasm. Alternatively, in the H_2 :heterodisulfide oxidoreductase, H_2 is oxidized by Vht/Vhx to produce two protons outside the cell and two electrons that are transferred to MPH_2 , which is then used to reduce CoM-S-S-CoB. The dashed arrow represents a third possible energy-conserving mechanism that is proposed in this study. In this pathway, $F_{420}H_2$ is oxidized by the cytoplasmic hydrogenase Frh to generate H_2 . The H_2 then diffuses outside the cell to the active site of membrane-bound hydrogenase Vht/Vhx, where it is oxidized, resulting in the translocation of two protons via a “ H_2 -cycling” mechanism. The electrons are passed through MP to CoM-S-S-CoB as in the other two systems. In all three systems, the entire electron transport process leads to the net translocation of four protons (highlighted in red) outside the cell per two electrons transferred from $F_{420}H_2$ or H_2 to the CoM-S-S-CoB. The electrochemical gradient generated is coupled to ATP synthesis via an A-type ATPase. Abbreviations are same as in Figure 1; FAD, flavin adenine dinucleotide; [FeS], iron-sulfur cluster; [NiFe], bimetallic catalytic center; Cyt_b₂, cytochrome *b*₂.

oxidoreductase system, MPH_2 passes electrons to CoM-S-S-CoB, leading to translocation of two additional protons. *In vitro* measurements suggest that the

magnitude of proton motive force generated is the same for both oxidoreductase systems, probably $4\text{H}^+/2\text{e}^-$ (3, 22).

The F_{420}H_2 :heterodisulfide oxidoreductase system shares features with the aerobic electron transport chain found in many bacteria. Fpo was purified from *M. mazei* Gö1 as a five subunit complex (FpoBCDIF) capable of oxidizing F_{420}H_2 with a variety of artificial electron acceptors (1). Most of these proteins were later shown to be encoded by a 13-gene operon, *fpoABCDHIJJKLMNO* (*fpo*), with *fpoF* being located elsewhere on the genome (Figure 2.3) (3). Fpo

Figure 2.3 (cont.)

C

Figure 2.3 (cont.)

Figure 2.3 Genomic organization of operons encoding F₄₂₀-phenazine oxidoreductase (Fpo), F₄₂₀-reducing hydrogenase (Frh) and heterodisulfide reductase (Hdr) in *Methanosarcina* species.

Panel A depicts the 13-gene operon (*fpoABCDHIJJKLMNO*) that encodes the hydrophilic (FpoO), membrane-associated (FpoBCDI) and membrane-integral modules (FpoAHJKLMN) of Fpo in the three species. As is evident, *M. acetivorans* harbors two copies of *fpoO*, *fpoO1* and *fpoO2*, and *fpoP* that is not present in the other two *Methanosarcina* species. Panel B depicts the gene (*fpoF*) that encodes the input module of Fpo (FpoF). In all three species, *fpoF* is located between genes encoding methylene-tertrahydrosarcinapterin reductase (*mer*) and a putative cytidyltransferase (28). These genes may constitute an operon. Panel C depicts the F₄₂₀-reducing hydrogenase operons (*frhADGB*) in the three species. *M. barkeri* has two of these operons, *frhADGB* and *freAEGB*. The *freAEGB* operon lacks gene D that encodes a putative hydrogenase maturation protein presumed to be essential for post-translational modification of the *cis*-encoded hydrogenase. Panel D depicts the operons encoding heterodisulfide reductase (HdrED) in the three species. Other open reading frames (ORFs) are shown as gray arrows.

shares significant homology with NADH dehydrogenase I (Nuo) of *Escherichia coli* and the nomenclature reflects that similarity. Accordingly, both Fpo and Nuo are composed of similar membrane-integral (the A, H, J, K, L, M and N subunits) and membrane-associated (the B, C, D and I subunits) modules. However, the enzymes differ in their substrates and hence in their input modules, such that

NuoEFG oxidizes NADH, whereas FpoF oxidizes $F_{420}H_2$, which is a hydride carrier analogous to NADH (11).

The source of electrons for the two disparate *Methanosarcina* electron transport chains varies with the growth substrate (Figure 2.1). During growth on H_2/CO_2 (the hydrogenotrophic pathway), or on H_2 in combination with a C-1 electron acceptor (the methyl-espersion pathway), electrons are derived from H_2 oxidation and are utilized via the H_2 :heterodisulfide oxidoreductase system (11). Genetic and biochemical experiments in *M. barkeri* suggest that use of acetate (the aceticlastic pathway) also involves the obligate intermediacy of H_2 and the H_2 :heterodisulfide oxidoreductase system (31, 32). In contrast, metabolism of compounds such as methanol or methylamines (the methylotrophic pathway) produces two equivalents of $F_{420}H_2$ per C-1 molecule oxidized. Thus, it has been suggested that $F_{420}H_2$:heterodisulfide oxidoreductase system plays a central, perhaps essential, role in the energy-conserving electron transport chain of the methylotrophic pathway in all *Methanosarcina* species (reviewed in (10, 11, 14, 15, 22)).

Surprisingly, the *in vivo* genetic data presented here tell a different story. Contrary to expectations, Fpo is not required for growth under any condition tested, including during growth on methanol. Instead, reducing equivalents from methanol oxidation appear to be preferentially passed to molecular H_2 by the cytoplasmic F_{420} -reducing hydrogenase (Frh). Subsequently, H_2 may enter into the electron transport chain via the H_2 :heterodisulfide oxidoreductase system (Figure 2.2). These data are reminiscent of the “hydrogen-cycling” model for

electron transport first proposed by Odom and Peck for sulfate-reducing bacteria (37) and suggest that a reanalysis of energy conservation mechanisms in freshwater *Methanosarcina* species is warranted.

2.3 MATERIALS AND METHODS

2.3.1 Sequence analysis

All sequence data are from publicly available genomes (3, 11, 17, 27). The Integrated Microbial Genome (IMG) system was used to identify orthologs and assess the genomic context of genes (28). Protein sequences were aligned using ClustalW (<http://www.ebi.ac.uk/Tools/clustalw2>).

2.3.2 Media and growth conditions

Methanosarcina strains were grown as single cells (47) at 37°C in high salt (HS) broth medium (30) or on agar-solidified medium as described (6). Growth substrates provided were methanol (125 mM) or sodium acetate (120 mM) under a headspace of either N₂/CO₂ (80/20%) mix at 50 kPa over ambient pressure or H₂/CO₂ (80/20%) mix at 300 kPa over ambient pressure. Puromycin (CalBioChem, San Diego, CA) was added at 2 µg/ml for selection of the puromycin transacetylase (*pac*) gene (42, 43). 8-Aza-2,6-diaminopurine (8-ADP) (Sigma, St Louis, MO) was added at 20 µg/ml for selection against the presence of *hpt* (43). Standard conditions were used for growth of *E. coli* strains (53) DH5α/*λ*-*pir* (34) and DH10B (Stratagene, La Jolla, CA), which were used as hosts for plasmid constructions.

2.3.3 DNA methods and plasmid constructions

Standard methods were used for plasmid DNA isolation and manipulation in *E. coli* (2). Liposome mediated transformation was used for *Methanosarcina* as described (29). Genomic DNA isolation and DNA hybridization were as described (6, 30, 56). DNA sequences were determined from double-stranded templates by the W.M. Keck Center for Comparative and Functional Genomics, University of Illinois. Plasmid constructions are described in Tables 2.1 and 2.2.

2.3.4 Construction of *M. barkeri* Fusaro deletion mutants

The construction and genotype of all *Methanosarcina* strains is presented in Table 2.3. The markerless genetic exchange method (43) was employed to delete *fpoA-O* operon (*fpo*), *fpoF* and *freAEGB* operon (*fre*) in the Δhpt (WWM85 or WWM86) (20) background of *M. barkeri* Fusaro. DNA sequences immediately flanking the deleted genes were left intact to exclude loss of regulatory elements needed for expression of adjacent genes. The plasmids, pDK4, pDK13 and pGK6 were used to delete *fpoA-O* in WWM86, *fpoF* in WWM85 and *fre* in WWM85, respectively on methanol plus H₂/CO₂ as the growth substrate. The *frhADGB* operon (*frh*) was deleted in the Δhpt (WWM86), Δfpo (WWM71) and $\Delta fpoF$ (WWM123) backgrounds of *M. barkeri* Fusaro by the homologous recombination-mediated gene replacement method (56). In this method, *Apal*/*NotI*-cut 5.5 kb region of pAMG81 was transformed into Δhpt , Δfpo and $\Delta fpoF$ mutants and the transformants were selected on methanol plus H₂/CO₂ and puromycin to obtain Δfrh (WWM122), $\Delta fpo \Delta frh$ (WWM108), $\Delta fpoF \Delta frh$

(WWM145) mutants, respectively. The Δfpo , $\Delta fpoF$, Δfrh , $\Delta fpo \Delta frh$ and $\Delta fpoF \Delta frh$ mutants were isolated and verified with DNA hybridization by Kridelbaugh *et al* (23). The Southern hybridization blot confirming Δfre mutant, which was isolated in this study, is shown in Figure 2.4. All genetic manipulations were carried out using methanol plus H_2/CO_2 as the growth substrate because the $F_{420}H_2$:heterodisulfide oxidoreductase system was not expected to be required for growth via the methyl-respiration pathway.

Figure 2.4 Verification of Δfre by Southern hybridization. Predicted bands (kb): **EcoRV**: WT (WWM85) = 6.3, mutants (1 and 2) = 2.9; **XbaI**: WT = 4.6 and 0.5, mutants = 1.1 and 0.5. MW: DIG-labeled DNA molecular weight marker III (Roche, Indianapolis, IN). 520 bp fragment of NdeI-digested *fre* deletion plasmid (pGK6, Table 2.1) was used as probe.

2.3.5 Determination of growth characteristics

Growth rate determination of Δfpo , $\Delta fpoF$, Δfrh , $\Delta fpo \Delta frh$ and $\Delta fpoF \Delta frh$ mutants was done by Kridelbaugh *et al* (23), whereas, Δfre growth was quantified in this study. The mutant was initially adapted to all substrates for at least 15 generations till mid-log phase (optical density at 600 nm [OD₆₀₀] *ca.* 0.5 for methanol and methanol/H₂/CO₂ and *ca.* 0.25 for H₂/CO₂ and acetate). Subsequently, approximately 3% inoculum (or 10%, in case of H₂/CO₂ and acetate) of the culture was transferred to fresh medium in quadruplets and incubated at 37°C. Growth was quantified by measuring OD₆₀₀. Generation times were calculated during exponential growth phase, growth yield was determined by measuring the maximal OD₆₀₀ of the culture and lag phase was defined as the time required to achieve half-maximal OD₆₀₀.

2.3.6 Cell suspension experiments

Cells grown on methanol plus H₂/CO₂ were collected in late exponential phase (OD₆₀₀= 0.6-0.7) by centrifugation at 5000 x g for 15 minutes at 4°C. They were then washed with anaerobic HS PIPES buffer, 50 mM PIPES (pH 6.8), 400 mM NaCl, 13 mM KCl, 54 mM MgCl₂, 2 mM CaCl₂, 2.8 mM cysteine, 0.4 mM Na₂S, and resuspended in the same buffer to a final concentration of 10⁹ cells/ml. Cells were counted visually using the Petroff-Hausser counting chamber (Hausser Scientific, PA). Assay mixtures contained 2 ml of the suspension and were incubated under strictly anaerobic conditions in 25 ml Balch tubes sealed with butyl rubber stoppers. Puromycin (20 µg/ml) or Mupirocin (pseudomonic

acid, 105 µg/ml, Sigma-Aldrich, St Louis, MO) (6) was added to prevent protein synthesis and, as indicated, the assay mixture contained 250 mM methanol under a headspace of N₂, H₂ or H₂/CO₂ (80/20%) at 250 kPa over the ambient pressure. Cells were held on ice until use and assays were started by transferring to 37°C. For rate determination, gas phase samples were withdrawn at various time points and assayed for CH₄ by gas chromatography at 225°C in a Hewlett Packard gas chromatograph (5890 Series II) equipped with a flame ionization detector. The column was of stainless steel filled with 80/120 CarbowaxTM B/3% SPTM-1500 (Supelco, Bellefonte, PA) with helium as the carrier gas. For total CH₄ and CO₂ production, assays were incubated at 37°C for 36 hours and then gas phase samples were withdrawn and analyzed by GC at 225°C in a Hewlett Packard gas chromatograph (5890 Series II) equipped with a thermal conductivity detector. A stainless steel 60/80 Carboxen-1000 column (Supelco, Bellefonte, PA) with helium as the carrier gas was used. Total cell protein was determined using the Bradford (7) method after 1 ml of the cells was lysed by resuspending it in ddH₂O with 1 µg/ml RNase and DNase.

2.3.7 RNA isolation and quantitative RT-PCR

Cultures grown to mid-exponential phase (OD₆₀₀ ca. 0.28 for *Δfrh* and ca. 0.4 for other strains) on methanol were lysed using three volumes of TRIzol LS Reagent (Invitrogen, Carlsbad, CA), followed by phase separation using chloroform as per manufacturer's instructions. Subsequently, RNA was precipitated using one volume of 70% ethanol and purified using RNeasy mini

spin columns (Qiagen, Valencia, CA) according to manufacturer's protocol. Contaminating DNA was removed by treatment with TURBO DNA-free DNase (Ambion, Austin, TX). The concentration and purity of RNA were evaluated using a NanoDrop spectrophotometer (NanoDrop, Wilmington, DE).

Gene-specific primers (Table 2.2) were designed using Primer Express Software v2.0 (Applied Biosystems, Foster City, CA). A one-step qRT-PCR reaction was performed using SuperScript III Platinum SYBR Green One-Step qRT-PCR Kit with ROX (Invitrogen, Carlsbad, CA) in the ABI PRISM 7900HT Sequence Detection System (Applied Biosystems). All reactions (20 μ l) contained 1X SYBR Green Reaction Mix with ROX, 0.4 μ l SuperScript III RT/Platinum Taq mix, 100 ng RNA and 10pmol each of primers. Synthesis of cDNA from RNA and subsequent amplification were performed as follows: 50°C for 5 min and 95°C for 2 min, followed by 40 cycles of 95°C for 15 s and 60°C for 1 min. Two negative controls, one without reverse transcriptase and another without template RNA, were run to check for DNA or RNA contamination.

The relative standard curve method was used to quantify expression of *fpo* (ABI PRISM 7700 Sequence Detection System User Bulletin #2) using *rpoA1* as the reference gene. In this, standard curves relating C_T values versus log amount of RNA were constructed for *fpo* and *rpoA1* using RNA isolated from methanol-grown WWM85 (Table 2.3). The *fpo* RNA amount in each sample was calculated using linear regression of the standard curve and averaged across triplicates of three biological samples for each culture. The average *fpo* amount was normalized to average *rpoA1* amount to obtain the relative *fpo* amount. This

value was divided by the calibrator value (WWM85) to obtain *fpo* fold regulation from wild-type.

2.4 RESULTS

2.4.1 The F₄₂₀H₂:heterodisulfide oxidoreductase is conserved in all sequenced *Methanosarcina* genomes

The genomes of *M. barkeri* Fusaro (27) and *M. acetivorans* C2A (17) encode *fpoABCDHIJJKLMNO* and *fpoF* operons that are nearly identical to those found in *M. mazei* Gö1 (Figure 2.3) (28). To test *in silico* if the operons from *M. barkeri* and *M. acetivorans* encode a functional Fpo, the predicted protein sequences of Fpo subunits from all three *Methanosarcina* species were aligned and analyzed for presence of conserved structural and catalytic amino acid residues that are present in *M. mazei* Fpo subunits (Figure 2.5).

The input module of Fpo, FpoF, has been proposed to oxidize F₄₂₀H₂ and transfer electrons via enzyme-bound FAD to two [4Fe-4S] clusters that are bound to FpoF by cysteine-containing motifs, C¹⁴XXC¹⁷XXC²⁰XXXC²⁴P and C⁵⁵XXC⁵⁸XXC⁶¹XXXC⁶⁵P, which are conserved in all three *Methanosarcina* FpoF subunits (3) (Figure 2.5). These subunits show 86-89% amino acid identity among each other (Table 2.4). Interestingly, the genomic location of *fpoF* is conserved in all three species, such that it is located between genes encoding methylenetetrahydrosarcinapterin reductase (*mer*) and a putative cytidylyltransferase (28) (Figure 2.6). Although it is unknown if the three genes constitute an operon, the *mer-fpoF* intergenic region in all three *Methanosarcina*

species includes multiple poly-T tracts, which are known to signal transcription termination in Archaea (44).

Figure 2.5 F₄₂₀:phenazine oxidoreductase (Fpo) subunit alignments. Inferred protein sequences were aligned using ClustalW for each Fpo subunit from *M. barkeri* (Mb), *M. mazei* (Mm) and *M. acetivorans* (Ma). Green bases denote conserved amino acid residues. Red bases highlighted in yellow are proposed to coordinate iron-sulfur centers or bind the substrate methanophenazine (MP). Refer to text for Fpo sequence analysis.

Table 2.4 Pairwise percent identities^a of *M. barkeri* (Mb) Fpo, *M. acetivorans* (Ma) Fpo, *M. mazei* (Mm) Fpo^b and *E. coli* (Ec) Nuo predicted protein sequences

^aClustalW was used for determination of percent identity.

^bLocus tags for genes encoding Fpo subunits are given in Figure 2.3.

Electrons from FpoF are probably channeled through the membrane-associated module of Fpo, Fpo BCDI, via three tetranuclear iron-sulfur clusters in FpoI and FpoB. Two of these [4Fe-4S] clusters are bound to FpoI by motifs, C⁴⁴XXC⁴⁷XXC⁵⁰XXXC⁵⁴P and C⁸⁴XXC⁸⁷XXC⁹⁰XXXC⁹⁴P (Figure 2.5), and are presumed to be analogous to the N6a and N6b clusters of Nuo of *Escheichia coli*. On the other hand, the third [4Fe-4S] cluster has been compared to the N2 cluster of Nuo of *E.coli* and probably binds FpoB via the motif, C⁶¹C⁶²XXEX₆₀C¹²⁶X₂₉C¹⁵⁶P. All three [4Fe-4S] cluster binding motifs are well-conserved in the three *Methanosarcina* FpoI and FpoB subunits (3, 10, 11). These subunits show a high degree of amino acid sequence identity (>83%) among each other (Table 2.4). Although the amphipathic subunits FpoC and FpoD do not have well-defined functions, FpoD has been implicated in binding MP aromatic rings via the conserved glycine³⁶⁷ residue. FpoD also contains two conserved cysteines, C⁷⁰ and C³⁶⁸, which are reminiscent of its ancestral protein, the large subunit of [NiFe] hydrogenases that harbors these cysteines as Ni-

binding ligands (11) (Figure 2.5). Both the FpoC and FpoD subunits from the three *Methanosarcina* species show significant amino acid sequence identity of 80-90% (Table 2.4). Another Fpo subunit that has eluded characterization is the hydrophilic FpoO subunit. In *M. mazei*, FpoO contains a [2Fe-2S] binding motif,

SC⁵⁸RXGXC⁶³SXC⁶⁶XXKX₂₄C⁹⁴ (3) (Figure 2.5). The four cysteines of the motif

that coordinate the iron-sulfur center are conserved in the other two

Methanosarcina species. However, *M. acetivorans* is missing the serine⁶⁴ residue

and *M. barkeri* the glycine⁶¹ and serine⁶⁴ residues. *M. acetivorans* has an

additional copy of *fpoO* (*fpoO2*) that is *ca.* 3 kb downstream of the first copy in the *fpo* operon (*fpoO1*) (28) (Figure 2.3). Both FpoO subunits show 79% amino acid identity, however, FpoO2 is missing one of the cysteines (C⁹⁴) that coordinates the putative iron-sulfur cluster. The FpoO subunits from *M. mazei* and *M. acetivorans* show 80% amino acid identity, however, *M. barkeri* FpoO shows only *ca.* 60% identity to the other two FpoO subunits.

Electrons from FpoF through FpoI and then FpoB are thought to be transferred to the membrane-integral module of Fpo, FpoAHJKLMN, which uses them to reduce MP by a yet unknown mechanism (10). All hydrophobic Fpo subunits possess 77-99% amino acid sequence identity among the three *Methanosarcina* species (Table 2.4). Also, in all the species, FpoJ is encoded by two contiguous *fpoJ* genes, such that the first gene encodes a protein that is homologous to the amino terminus of NuoJ, while the second one encodes a protein that is homologous to the carboxyl-terminus of NuoJ (28). Interestingly, *M. acetivorans* Fpo has been proposed to contain a small additional subunit, FpoP, when grown on CO as the growth substrate (24). However, there is no experimental evidence that FpoP protein is produced, nor is the gene conserved in the other two *Methanosarcina* species (28). Thus it is still unknown if FpoP has a role in methanogenesis from any substrate.

In conclusion, the *in silico* analysis of Fpo predicted protein sequences from the three *Methanosarcina* species shows conservation of all important catalytic and structural residues in the proteins suggesting that like *M. mazei* Fpo, Fpo enzymes from *M. barkeri* and *M. acetivorans* might also be functional.

Further, each sequenced genome carries homologs of the *hdrDE* operon, which encodes the methanophenazine-linked heterodisulfide reductase (Figure 2.3) (13, 17, 27, 28). Thus, although biochemical activity has only been examined in *M. mazei*, functional F₄₂₀H₂:heterodisulfide oxidoreductase systems are probably present in each of the *Methanosarcina* species examined to date.

2.4.2 F₄₂₀H₂ dehydrogenase is not required for methanogenesis or growth in *M. barkeri*

As described above, *in vitro* biochemical experiments led to the suggestion that the F₄₂₀H₂:heterodisulfide oxidoreductase system should be essential for growth on C-1 compounds via the methylotrophic pathway. To test this *in vivo*, we constructed *M. barkeri* mutants lacking F₄₂₀H₂ dehydrogenase by deleting the *fpoA-O* operon or the *fpoF* gene (Table 2.3).

The $\Delta fpoA-O$ and $\Delta fpoF$ mutants were tested for their ability to grow on various methanogenic substrates (Table 2.5). As expected, both mutants grow on H₂/CO₂, methanol plus H₂/CO₂ and acetate with growth rates and yields similar to the isogenic parental strain. However, we were surprised to discover that growth of the mutants on methanol was also unaffected. Further, CH₄ and CO₂ were produced by the $\Delta fpoA-O$ and $\Delta fpoF$ mutants in the expected 3:1 stoichiometry in amounts and at rates similar to the parent on all substrates (Tables 2.6 & 2.7). Thus, loss of F₄₂₀H₂ dehydrogenase, and therefore of the F₄₂₀H₂:heterodisulfide oxidoreductase system, does not measurably affect methanogenesis or growth of *M. barkeri*.

2.4.3 Frh is essential for growth of *M. barkeri* on H₂/CO₂ and plays an important role in the methylotrophic pathway

The dispensability of Fpo raises the question of which enzyme(s) transfers electrons from F₄₂₀H₂ to MP in the methylotrophic pathway. Because *M. barkeri* possesses a highly active F₄₂₀-reducing hydrogenase (Frh) (33), we considered the possibility of electrons being channeled from F₄₂₀H₂ into the H₂:heterodisulfide oxidoreductase system via production of H₂ by Frh (Figure 2.2).

The F₄₂₀-reducing hydrogenase couples oxidation of H₂ to F₄₂₀ reduction *in vitro* and is fully reversible (9, 33, 52). *M. barkeri* has two operons, *frhADGB*

and *freAEGB*, with the potential to encode F₄₂₀-reducing hydrogenases (Figure 2.3) (51). It is unclear whether *freAEGB* encodes an active hydrogenase, because it lacks the required maturation protease, encoded by *frhD* in the homologous operon. Nevertheless, the putative *fre*-encoded hydrogenase shares all important catalytic and structural amino acid residues with the *frh*-encoded enzyme. Thus, *freAEGB* could encode a functional F₄₂₀-reducing hydrogenase if the FrhD protease can function *in trans* (18). The F₄₂₀-reducing hydrogenase is proposed to provide F₄₂₀H₂, which is needed for CO₂ reduction in the hydrogenotrophic pathway (Figure 2.1) (33); however, *frhADGB* and *freAEGB* are expressed during growth on both H₂/CO₂ and methanol (18, 51). Thus, it seems possible that these genes play a role in both the hydrogenotrophic and methylotrophic pathways.

To test this, the *freAEGB* or *frhADGB* operons were deleted from the chromosome of *M. barkeri* (Table 2.3) and the resulting mutants characterized. The Δfre mutant is indistinguishable from its parent with respect to growth rate and yield on all substrates tested (Table 2.5). Further, deletion of *fre* from *M. barkeri* does not affect amount and rate of CH₄ produced in resting cell suspensions from the various substrates, nor does the mutation change the expected 3:1 ratio of CH₄ to CO₂ on methanol (Tables 2.6 & 2.7). These data indicate that Fre is not required for growth of *M. barkeri* on any of the substrates tested.

In contrast, the Δfrh mutation has severe phenotypic consequences on several of the growth media examined (Tables 2.5, 2.6 & 2.7). While the Δfrh

mutant is indistinguishable from its parent when grown on methanol plus H_2/CO_2 and acetate, it is unable to grow on H_2/CO_2 . Moreover, the Δfrh mutant has a two-fold slower growth rate and a 50% reduction in growth yield when methanol alone is used as a substrate. The Δfrh mutant exhibits a very long lag phase of 911 ± 21 hours (h) as compared to 31 ± 0.4 h for wild-type *M. barkeri* on methanol. The growth defects of the Δfrh mutant are further reflected in CH_4 production. Resting cell suspensions of the Δfrh mutant produce negligible amounts of CH_4 from H_2/CO_2 , and while they disproportionate methanol in the expected 3:1 ratio, they consistently produce only half as much CH_4 and CO_2 as the parent. Finally, the Δfrh mutation lowers rate of CH_4 production from methanol in resting cells ca. four-fold relative to the parent.

Taken together, these data indicate that Frh is essential for growth by the hydrogenotrophic pathway and plays an important, but dispensable, role in the methylotrophic pathway; the latter potentially being the delivery of electrons from F_{420}H_2 into the H_2 :heterodisulfide oxidoreductase system. Importantly, Fre is not able to substitute for the role of Frh under the conditions tested, suggesting that it does not encode a functional F_{420} -reducing hydrogenase in the absence of *frhADGB*.

2.4.4 *M. barkeri* possesses two functional pathways for electron transfer from F_{420}H_2 to MP

The fact that the Δfrh mutant retains the ability to grow and produce CH_4 from methanol, although at reduced rates, suggests that the cell has an alternative, less efficient route to deliver electrons from F_{420}H_2 to the CoM-S-S-

CoB heterodisulfide. The most obvious candidate for this electron transfer pathway is the $F_{420}H_2$:heterodisulfide oxidoreductase system. To test this hypothesis, we constructed and characterized double mutants lacking *frhADGB* and either *fpoA-O* or *fpoF* (Tables 2.3, 2.5, 2.6 & 2.7).

Like the single Δfrh mutant, the $\Delta fpoA-O \Delta frh$ and $\Delta fpoF \Delta frh$ double mutants are unable to grow on H_2/CO_2 and produce negligible amounts of CH_4 in resting cell suspensions from this substrate. Both mutants are able to grow and produce CH_4 at levels and rates comparable to the parent on methanol plus H_2/CO_2 . However, in contrast to the Δfrh , $\Delta fpoA-O$ and $\Delta fpoF$ single mutants, the double mutants are incapable of growth on methanol. Thus, Frh and Fpo fulfill a similar role during growth on this substrate that is lost in the absence of both enzymes. Quantitative RT-PCR experiments show that although *fpoA-O* transcripts levels are slightly higher in the Δfrh mutant (3.9 ± 1.5 fold), they are easily detectable in the parental strain (Δhpt , WWM85), $\Delta fpoF$ and Δfre (Table 2.8). Therefore, Fpo is expressed and has the potential to contribute to the methylotrophic electron transport chain in wild-type *M. barkeri* as well. Interestingly, the $\Delta fpoA-O \Delta frh$ and $\Delta fpoF \Delta frh$ mutants still produce small amounts of CH_4 and CO_2 from methanol despite their inability to grow on this substrate. Hence, an additional minor electron transport pathway(s) exists in *M. barkeri* that is incapable of supporting growth.

Surprisingly, the double mutants display different phenotypes when grown on acetate. The $\Delta fpoF \Delta frh$ mutant grows slowly on acetate, whereas the $\Delta fpoA-O \Delta frh$ mutant is unable to utilize acetate. It is unclear how absence of both Fpo

and Frh affects growth on acetate because neither the $\Delta fpoA$ -O nor the Δfrh single mutant exhibits a growth defect on this substrate. These data seem to suggest that the input module of Fpo (FpoF) can be dispensable under conditions in which the proton-pumping methanophenazine oxidoreductase (FpoABCDHIJKLMNO) is not.

Table 2.8 Relative abundance of *fpoA*-O transcript^a in methanol grown *M. barkeri* Fusaro mutants^b as compared to the parent strain

Strain	Fold-expression ^c
Δfpo	0
$\Delta fpoF$	1.7±0.6

^c Experiment was conducted and calculations were done as described in Materials and Methods. NG, no growth.

2.5 DISCUSSION

Methanosarcina species have proven to be exceptional model organisms for genetic analysis of methanogenesis (19, 32, 54, 55), an approach that modified our concept of energy conservation in *M. barkeri*. The data presented here indicate that *M. barkeri* has two distinct energy-conserving electron

transport pathways during growth via the methylotrophic methanogenic pathway (Figure 2.2). Contrary to expectations, *M. barkeri* apparently prefers to transfer electrons obtained from C-1 compound oxidation to the H₂:heterodisulfide oxidoreductase system via H₂, rather than to transfer them directly into the F₄₂₀H₂:heterodisulfide oxidoreductase system. Our results suggest that the cytoplasmic F₄₂₀-reducing hydrogenase (Frh) mediates electron transfer to H₂ via oxidation of F₄₂₀H₂, which, along with Fd_{red}, is the direct product of C-1 compound oxidation (33, 52). When the cells lose the ability to produce H₂ via this route, growth on methanol is severely affected, with reduction in the rates of growth and CH₄ production, as well as reduction in total growth yield and amount of CH₄ produced. We suggest that the H₂ diffuses out of the cell where it enters the H₂:heterodisulfide oxidoreductase system via methanophenazine-dependent hydrogenase (Vht or Vhx (18)), whose active site is known to be in the periplasm (10). Because production of H₂ by Frh consumes protons within the cytoplasm, while oxidation of H₂ by Vht/Vhx releases protons outside the cell, this electron transport chain is capable of establishing a proton gradient across the membrane that can be used to generate ATP by the ATP synthase (35), thus conserving energy via a H₂-cycling mechanism (37). *M. barkeri* genome harbors two operons, *vhtGACD* and *vhxGAC*, that can potentially encode methanophenazine-dependent hydrogenases. Analogous to the *fre* operon, the *vhx* operon lacks gene D that encodes the hydrogenase maturation protease and therefore may not encode a functional hydrogenase. However, Vhx shares all important catalytic and structural amino acid residues with Vht and could encode

an active methanophenazine-dependent hydrogenase if the VhtD protease can function *in trans* (18).

H₂-cycling, as a mechanism of energy conservation, was first proposed in sulfate-reducing bacteria (37). Later, it was also proposed in other anaerobic organisms like *Acetobacterium woodii* (38) and *Geobacter sulfurreducens* (8). Based on the production of H₂ during growth of *Methanosarcina* species on methylated substrates like methanol, trimethylamine and acetate, H₂-cycling was also suggested to occur in *Methanosarcina* (26). Experimental support for H₂-cycling has been provided in *Desulfovibrio vulgaris*, wherein simultaneous production and consumption of H₂ were detected during metabolism of pyruvate and sulfate (41). Also, suppression of a *D. vulgaris* H₂-evolving hydrogenase led to reduced growth rates on lactate and sulfate, suggesting the importance of H₂ production in growth (50). Nevertheless, the H₂-cycling theory is not universally accepted and several lines of evidence have been used to argue that this mechanism is unlikely (reviewed in (36)). For example, high concentrations of H₂ do not inhibit lactate oxidation in sulfate-reducing bacteria (40), nor does a mutation that blocks use of H₂ prevent growth on lactate (39). Further, the idea that the cell would preferentially transfer electrons to a molecule that can freely diffuse away from the cell seems highly problematic.

The data presented here suggest a way to reconcile these conflicting views. While *M. barkeri* apparently prefers to transfer electrons via H₂, they remain capable of using the F₄₂₀H₂:heterodisulfide oxidoreductase system when the ability to produce cytoplasmic H₂ is lost. Thus, *M. barkeri* employs a

branched electron transport chain with most electrons flowing from $F_{420}H_2$ into the H_2 :heterodisulfide oxidoreductase system via H_2 , but with some fraction flowing directly into the $F_{420}H_2$:heterodisulfide oxidoreductase system. A similar branched electron transport chain in sulfate reducers would explain the results cited above as arguing against H_2 -cycling without invalidating the model. It should be noted that a recently proposed metabolic model for *D. vulgaris* suggests just such a branched electron transport chain (36).

Why then is H_2 -cycling pathway the preferred electron transport chain in *M. barkeri*? Because the initial electron donor ($F_{420}H_2$) and final electron acceptor (MP) are the same, the amount of energy available from the two electron transport schemes must be identical. Experimental measurements suggest that electron transfer from $F_{420}H_2$ to CoM-S-S-CoB via Fpo and Hdr is accompanied by translocation of four protons across the membrane (3). Similarly, flow of electrons from $F_{420}H_2$ to MP via Frh and Vht/Vhx leads to translocation of two protons across the membrane by virtue of the H_2 -cycling mechanism, while electron transfer from MPH_2 to CoM-S-S-CoB translocates another two protons (22). Thus, the magnitude of proton motive force generated should be identical via either route, Figure 2.2. In contrast, the rate of CH_4 production from methanol in resting cell suspensions of Δfrh mutant is *ca.* four times slower than that of $\Delta fpoA-O$ and $\Delta fpoF$ mutants. This indicates that H_2 -cycling is a much faster mechanism of energy conservation and, as observed in our mutant strains, allows correspondingly faster growth rates. The biochemical properties of the enzymes involved are remarkably consistent with our *in vivo* data. Thus,

FpoBCDIF (Molecular weight, MW = 135.1 kDa (3)) purified from *M. mazei* catalyzes $F_{420}H_2$ oxidation with a turnover number (K_{cat}) of 38 s^{-1} and catalytic efficiency (K_{cat}/K_m) of $5.4 \times 10^6\text{ M}^{-1}\text{ s}^{-1}$ (1). Whereas, FrhAGB (MW = 194.4 kDa (51)) purified from *M. barkeri* catalyzes H_2 oxidation using F_{420} as the electron acceptor with a K_{cat} of 134 s^{-1} and K_{cat}/K_m of $4.4 \times 10^7\text{ M}^{-1}\text{ s}^{-1}$ (33). Because methanol-metabolizing *M. barkeri* cells have been shown to maintain ratios of $F_{420}H_2$ and F_{420} in thermodynamic equilibrium with the H_2 partial pressure (9), it is reasonable to assume that Frh catalyzes the reverse reaction ($F_{420}H_2$ oxidation) with similar efficiency as the forward reaction (H_2 oxidation). Therefore the turnover number of Frh is *ca.* four times higher than Fpo for $F_{420}H_2$ oxidation, implying that Frh is faster in catalyzing this reaction than Fpo.

A variety of data indicate that H_2 -cycling is important to many, but not all *Methanosarcina* species. Growth of *M. barkeri* on acetate involves the obligate intermediacy of H_2 (32). Thus, in combination with the data presented here, it seems likely that this species prefers to use H_2 cycling for all soluble substrates. The situation is probably similar in *M. mazei* as it has functional Frh, Vht and Fpo enzymes as well (3). However, methylotrophic species like *M. acetivorans* (17-19), *Methanlobus tindarius* (21, 46) and *Methanococcoides burtonii* (45) do not encode functional hydrogenases (28). Hence, these organisms probably rely exclusively on the $F_{420}H_2$:heterodisulfide oxidoreductase system for energy conservation. It has previously been suggested that these organisms forego H_2 -dependent electron transport pathways due to their high-salt marine habitat, wherein they exist as disaggregated single cells and would be prone to lose the

freely diffusible H₂ gas to competing organisms. In contrast, freshwater organisms like *M. barkeri* that exist as large multicellular aggregates, have a higher chance of retaining H₂ gas within the aggregates, enabling them to use it as an electron carrier (19).

Lastly, the phenotypes of the mutants constructed here also provide insight into the metabolism of H₂/CO₂ and acetate by *M. barkeri*. Due to its ability to catalyze F₄₂₀ reduction with H₂, F₄₂₀-reducing hydrogenase was proposed to provide F₄₂₀H₂ for reduction of methenyl-H₄SPT (tetrahydrosarcinapterin) and methylene-H₄SPT in the hydrogenotrophic pathway (Figure 2.1) (33, 48). The inability of the *frh* mutants to grow on H₂/CO₂ provides direct experimental support for this proposal. Interestingly, the putative *fre*-encoded hydrogenase cannot substitute for the *frh*-encoded hydrogenase. This may be due to low expression of *fre*, absence of post-translational processing, mutations in structural or catalytic residues, or some combination of these (18). Nevertheless, the dispensability of *fre* in *M. barkeri* is not surprising because *M. mazei* lacks the *fre* gene and is able to grow via all four methanogenic pathways (10, 18). Thus, the role of Fre in *M. barkeri* remains mysterious.

Methanogenesis from acetate does not require either Frh or Fpo; however, our results show that one of the two enzymes, but not both, is needed for growth on this substrate. We previously showed that mutations in the C-1 oxidation pathway prevent growth on acetate, presumably by blocking the production of reducing equivalents needed for biosynthetic reactions (55). The lack of growth of the $\Delta frh \Delta fpo$ double mutant on acetate medium suggests that

these reducing equivalents must flow through either Frh or Fpo to allow growth. Interestingly, the $\Delta frh \Delta fpoF$ double mutant is able to grow on acetate. This clearly suggests that the membrane-bound proton-pumping module has the ability to accept electrons from input modules other than FpoF. In this regard, FpoF is homologous to the β -subunit (B) of F_{420} -reducing hydrogenases, and shares a common substrate: coenzyme F_{420} (3, 51). It is conceivable that in the absence of FpoF and FrhB, FreB serves as the input module, thus channeling electrons from $F_{420}H_2$ to Fpo and allowing growth of $\Delta frh \Delta fpoF$ double mutant on acetate; however, this remains to be tested.

CHAPTER 3

DEMONSTRATION OF HYDROGEN CYCLING DURING ELECTRON TRANSPORT IN *METHANOSARCINA BARKERI*

3.1 ABSTRACT

In the preceding Chapter, *M. barkeri* was proposed to utilize the “H₂-cycling” mechanism for energy conservation during methylotrophic growth. Here, we provide direct experimental evidence for this proposal. The H₂-cycling pathway presumably involves two hydrogenases, the cytoplasmic F₄₂₀-dependent hydrogenase (Frh) that produces H₂ from reduced coenzyme F₄₂₀ (F₄₂₀H₂) within the cytosol, and the periplasmic methanophenazine-dependent hydrogenase (Vht) that consumes this H₂ within the periplasm to feed it into *M. barkeri* electron transport chain. Consistent with this role of Vht, we were unable to isolate a deletion mutant of the *vht* operon. Furthermore, a tetracycline-regulated conditional *vht* mutant is not able to grow using any of the methanogenic substrates tested, under non-permissive conditions. This suggests that Vht is essential for growth of wild-type *M. barkeri*. Repression of *vht* expression led to a rapid increase in H₂ partial pressure, which is consistent with a requirement for Vht in H₂ uptake. Moreover, H₂ accumulation also coincided with cessation of methanogenesis and growth, suggesting that H₂ uptake is essential for anaerobic respiration and viability. In contrast, Vht is not essential in mutants lacking the H₂-producing, cytoplasmic Frh. This is consistent with functional coupling of Frh and Vht hydrogenases in the H₂-cycling mechanism. Because production of H₂ by Frh consumes protons within the cytoplasm, whereas, oxidation of H₂ by Vht

releases protons outside the cell, this electron transport chain is capable of establishing a trans-membrane proton gradient that can be used to make ATP by the ATP synthase.

3.2 INTRODUCTION

Adenosine triphosphate (ATP) is the universal energy currency of cells. It is synthesized in two ways, substrate-level or electron-transport mediated phosphorylation of adenosine diphosphate (ADP). In the former, ATP is made in the cytosol using molecules with a high group transfer potential like acetyl-phosphate (51). The latter involves generation of a trans-membrane electrochemical ion (usually proton) gradient that can be used directly as a source of energy or indirectly by conversion to ATP using an ATP synthase. A proton gradient is created during electron transfer in either of the two ways: vectorial pumping of protons outside the cell or their scalar movement across the membrane due to consumption of protons within the cell and production outside it, as in a quinone-loop (52).

In 1981, Odom and Peck proposed a novel method of energy conservation, called H₂-cycling (36). In this, H₂ is produced by a cytoplasmic hydrogenase using protons within the cytosol. Subsequently, the H₂ diffuses to a periplasmic hydrogenase, where it is oxidized to regenerate protons. This creates a trans-membrane proton gradient that can be used to make ATP. Although H₂-cycling has been suggested to occur in a number of anaerobic organisms (8, 24, 36, 37), evidence in favor of the theory is limited and indirect. It includes

demonstration of simultaneous production and consumption of H_2 using membrane-inlet mass spectrometry during metabolism of pyruvate and sulfate by *Desulfovibrio vulgaris* (40). Also, reduction in growth rate of *D. vulgaris* on lactate and sulfate, due to reduced expression of the H_2 -evolving hydrogenase, has been observed (49). However, these supporting data have been clouded by conflicting reports, wherein, neither high concentrations of H_2 (39), nor a block in H_2 utilization inhibits lactate oxidation in sulfate-reducing bacteria (38). Thus, till date there is no direct experimental evidence for H_2 -cycling. Moreover, energy conservation using a diffusible molecule as an essential intermediate is considered highly implausible.

The methanogen, *Methanosarcina*, conserves energy via electron-transport mediated phosphorylation. Two electron transport chains have been identified in *Methanosarcina* species, H_2 :heterodisulfide and $F_{420}H_2$:heterodisulfide oxidoreductase systems (Figure 3.1). These involve electron transfer from H_2 or $F_{420}H_2$ to a heterodisulfide (CoM-S-S-CoB) of coenzyme M (CoM-SH) and coenzyme B (CoB-SH) (reviewed in (10, 11)). On the basis of biochemical evidence, $F_{420}H_2$:heterodisulfide oxidoreductase system was presumed to be utilized in the methylotrophic electron transport chain (3, 4, 13). However, evidence presented in Chapter 2 suggested that *M. barkeri* preferentially employs H_2 -cycling during methylotrophic growth (22). In the $F_{420}H_2$:heterodisulfide system, the $F_{420}H_2$ dehydrogenase (Fpo) is used for $F_{420}H_2$ oxidation, whereas, in the H_2 :heterodisulfide system, methanophenazine (MP)-dependent hydrogenase is used to oxidize H_2 . The deletion of *fpo* in *M. barkeri*

has no phenotypic consequences on any methanogenic substrate tested.

Instead, a knockout of *frh* that is unable to synthesize the F₄₂₀-reducing hydrogenase (Frh), displays severe growth defect on methanol. The Frh

Figure 3.1 The electron transport chain of *Methanosarcina barkeri* (adapted from (24)) has been proposed to comprise two energy-conservation systems, the F₄₂₀H₂:heterodisulfide oxidoreductase and the H₂:heterodisulfide oxidoreductase. In the former, F₄₂₀H₂ is oxidized by FpoF releasing two electrons that are transferred through FpoBCDI and then FpoAHJKLMN to membrane-soluble MP. This reaction is coupled to pumping of two protons outside the cell. Reduction of MP consumes two protons from the cytoplasm, which are subsequently released outside the cell upon oxidation of MPH₂. The electrons are then transferred through HdrED to reduce CoM-S-S-CoB with two protons from the cytoplasm. Alternatively, in the H₂:heterodisulfide oxidoreductase, H₂ is oxidized by Vht to produce two protons outside the cell and two electrons that are transferred to MP, which is then used to reduce CoM-S-S-CoB. The dashed arrow represents a third energy-conservation mechanism that is proved in this study. In this pathway, F₄₂₀H₂ is oxidized by the cytoplasmic hydrogenase Frh to generate H₂. The H₂ then diffuses outside the cell to the active site of membrane-bound hydrogenase Vht, where it is reoxidized, resulting in the translocation of two protons via a H₂-cycling mechanism. The electrons are passed through MP to CoM-S-S-CoB as in the other two systems. In all three systems, the entire electron transport process leads to the net translocation of four protons outside the cell per two electrons transferred from F₄₂₀H₂ or H₂ to CoM-S-S-CoB. The electrochemical gradient generated is coupled to ATP synthesis via an A-type ATPase. This study also presents evidence for involvement of the Ech hydrogenase in H₂-cycling (dotted line). Ech presumably couples the exergonic oxidation of Fd_{red} to H₂ formation, concomitantly pumping an unknown number of protons outside the cell. The proton-motive force is likely used for the transfer of methyl group from methyl-CoM to tetrahydrosarcinapterin. However, the H₂ may diffuse out to Vht and enter the H₂:heterodisulfide oxidoreductase system for energy conservation. Scalar or vectorial protons translocated across the cell membrane are highlighted in red. Abbreviations; Ech, Fd-dependent hydrogenase; Frh, F₄₂₀-reducing hydrogenase; Fpo, F₄₂₀H₂:phenazine oxidoreductase; Vht, methanophenazine-dependent hydrogenase; Hdr, heterodisulfide reductase; CoM-SH, coenzyme M; CoB-SH, coenzyme B; CoM-S-S-CoB, mixed disulfide of CoM-SH and CoB-SH; MP/MPH₂,

Figure 3.1 (cont.)

oxidized and reduced methanophenazine; Fd_{ox}/Fd_{red} , oxidized and reduced ferredoxin; $F_{420}/F_{420}H_2$, oxidized and reduced Factor 420; FAD, flavin adenine dinucleotide; [FeS], iron-sulfur cluster; [NiFe], bimetallic catalytic center; $Cytb_2$, cytochrome b_2 .

hydrogenase catalyzes the reversible reduction of F_{420} with H_2 (32). Therefore, Frh was proposed to oxidize $F_{420}H_2$ to H_2 during methylotrophic growth. The H_2 could be subsequently channeled via the MP-dependent hydrogenase into the H_2 :heterodisulfide oxidoreductase system. This also suggested that the cytoplasmic Frh hydrogenase and periplasmic MP-dependent hydrogenase might conserve energy via the H_2 -cycling mechanism. Nevertheless, it was shown that Fpo remains capable of directing electrons from $F_{420}H_2$ into the $F_{420}H_2$:heterodisulfide oxidoreductase system in the Δfrh mutant. Hence, *M. barkeri* was proposed to possess a branched electron transport chain on methanol, with one branch involving H_2 as an intermediate and another, the proton-pumping Fpo oxidoreductase (22).

The MP-dependent hydrogenase of *Methanosarcina* was characterized as part of the H_2 :heterodisulfide oxidoreductase system in *Methanosarcina mazei* Gö1 (9, 12, 20). This membrane-bound hydrogenase reduces the membrane soluble electron carrier MP using H_2 (5) and has therefore been proposed to provide reduced MP (MPH_2) for reduction of CoM-S-S-CoB heterodisulfide, in the hydrogenotrophic, methyl-respiration and acetoclastic pathways (10, 11, 31). *M. barkeri* contains two operons, *vhtGACD* and *vhxGAC*, encoding the two MP-dependent hydrogenases, Vht and Vhx, respectively (Figure 3.2). The deduced amino acid sequences of Vht and Vhx have all the important structural and

catalytic residues that are present in *M. mazei* hydrogenases, suggesting that these enzymes might also be functional as part of the H₂:heterodisulfide system.

Figure 3.2 Genomic organization of operons encoding methanophenazine-dependent hydrogenases in *Methanosarcina* species. Vho and Vht encoded by the *vhoGAC* and *vhtGACD* operons, respectively, of *M. mazei* are *ca.* 95% identical, however, Vhx encoded by *vhxGAC* shares only *ca.* 50% amino acid sequence identity to each of them. Both *M. barkeri* and *M. acetivorans* possess an operon similar to *vhtGACD* and another to *vhxGAC*. The *vho* and *vhx* operons lack gene D that encodes a putative hydrogenase maturation protein presumed to be essential for post-translational modification of the *cis*-encoded hydrogenase. All the three species also possess a *hypCDABE* operon that encodes proteins presumed to be required for synthesis and insertion of the [NiFe] bimetallic catalytic center in the hydrogenases of *M. barkeri*. Notably, *M. mazei* contains duplicate copies of *hypB* and *hypC* genes. Other open reading frames (ORFs) are shown as gray arrows.

Unlike the *vht* operon, the *vhx* operon is missing gene D that encodes a putative maturation protease. It has been proposed that *vhx*-encoded hydrogenase might be functional, if the protein encoded by *vhtD* can process it. However, the *vhx* operon is not expressed at detectable levels on any methanogenic substrate, whereas expression of *vht* is constitutive (16).

To test the role of Vht in H₂-cycling, we attempted deletion of the *vht* operon in *M. barkeri*. However, we discovered that Vht is essential for growth of wild-type *M. barkeri* under all conditions tested. Furthermore, repression of *vht* expression led to an increase in H₂ partial pressure in a conditional *vht* mutant. These results are consistent with a requirement for Vht in H₂ uptake. The accumulation of H₂ was also accompanied by growth inhibition, suggesting that H₂ uptake is essential for viability. However, Vht is not essential in mutants lacking the H₂-producing, Frh hydrogenase. This is consistent with the functional coupling of Frh and Vht in the H₂-cycling mechanism.

3.3 MATERIALS AND METHODS

3.3.1 Media and growth conditions

Methanosarcina strains were grown as single cells (46) at 37° C in high salt (HS) broth medium (28) or on agar-solidified medium as described (6). Growth substrates provided were methanol (125 mM in broth medium and 50 mM in agar-solidified medium) or sodium acetate (120 mM) under a headspace of either N₂/CO₂ (80/20%) mix at 50 kPa over ambient pressure or H₂/CO₂ (80/20%) mix at 300 kPa over ambient pressure. Cultures were supplemented as

indicated with 0.1% yeast extract, 0.1% casamino acids, 10 mM sodium acetate or 10 mM pyruvate. Puromycin (CalBioChem, San Diego, CA) was added at 2 µg/ml for selection of the puromycin transacetylase (*pac*) gene (42). 8-Aza-2,6-diaminopurine (8-ADP) (Sigma, St Louis, MO) was added at 20 µg/ml for selection against the presence of *hpt* (42). Tetracycline (Tc) was added at 100 µg/ml to induce the tetracycline-regulated *PmcrB(tetO)* promoter (18). Standard conditions were used for growth of *Escherichia coli* strains (50) DH5 α / λ -*pir* (33) and DH10B (Stratagene, La Jolla, CA), which were used as hosts for plasmid constructions.

3.3.2 DNA methods and plasmid constructions

Standard methods were used for plasmid DNA isolation and manipulation in *E. coli* (2). Liposome mediated transformation was used for *Methanosarcina* as described (27). Genomic DNA isolation and DNA hybridization were as described (6, 28, 53). DNA sequences were determined from double-stranded templates by the W.M. Keck Center for comparative and functional genomics, University of Illinois. Plasmid constructions are described in Tables 3.1 and 3.2.

3.3.3 Construction of Δvhx , Δfrh and $\Delta vht \Delta frh$ deletion mutants

The construction and genotype of all *Methanosarcina* strains is presented in Table 3.3. The markerless genetic exchange method (42) was employed to delete *vhx* and *frh* in the Δhpt (WWM85 or WWM86) background of *M. barkeri*

Table 3.1 Plasmids used in this study

Plasmid	Description and/or construction	Reference
pMP44	Vector, containing a <i>pac-hpt</i> cassette, used to delete genes from <i>M. barkeri</i> Fusaro chromosome using the markerless exchange method	(43)
pGK4	<i>AscI/KpnI</i> -digested <i>frh</i> upstream and downstream fusion PCR product amplified using primers <i>frhupfor</i> , <i>frhuprev</i> , <i>frhdnfor</i> and <i>frhdnrev</i> and ligated to <i>MluI/KpnI</i> -digested pMP44	This study
pGK5	<i>AscI/NotI</i> -digested <i>vht</i> upstream and downstream fusion PCR product amplified using primers <i>vhtupfor</i> , <i>vhtuprev</i> , <i>vhtdnfor</i> and <i>vhtdnrev</i> and ligated to <i>MluI/NotI</i> -digested pMP44	This study
pGK7	<i>AscI/NotI</i> -digested <i>vhx</i> upstream and downstream fusion PCR product amplified using primers <i>vh3upfor</i> , <i>vh3uprev</i> , <i>vh3dnfor</i> and <i>vh3dnrev</i> and ligated to <i>MluI/NotI</i> -digested pMP44	This study
pMR55	Non-replicating plasmid that contains the Flp recombinase gene under control of the <i>mcrB</i> promoter	(45)
pJK301	Vector, containing a <i>pac-hpt</i> cassette, used to delete genes from <i>M. barkeri</i> Fusaro chromosome using double homologous recombination-mediated gene replacement method	(54)

Fusaro. The plasmids, pGK4 and pGK7 were used to delete *frh* in WWM86 and *vhx* in WWM85, respectively, using methanol plus H₂/CO₂ as the growth substrate. The $\Delta vht \Delta frh$ mutant was constructed by deleting *vht* in the Δfrh markerless mutant by the homologous recombination-mediated gene replacement method (53). In this method, XhoI/NotI cut 5.6 kb region of pGK82B was transformed into the Δfrh mutant and the transformants were selected using methanol and puromycin. All the mutants were confirmed by DNA hybridization (Figures 3.3, 3.4 and 3.5).

Figure 3.3 Verification of Δvhx by Southern hybridization. Predicted bands (kb): **BglIII**: WT (WWM85) = 2.1 and 2, mutant (M) = 5.6 and 2.1; **HincII**: WT = 8 and 1.7, mutant = 3.9 and 1.7; **PvuII**: WT = 7.1, mutant = 3. MW: DIG-labeled DNA molecular weight marker III (Roche, Indianapolis, IN). 750-bp PCR product of pGK7 amplified with primers vho3southernfor and vho3southernrev was used as probe (Tables 3.1 and 3.2).

Figure 3.4 Verification of Δfrh by Southern hybridization. Predicted bands (kb): **EcoRI**: WT (WWM86) = 5.4, mutants (1 and 2) = 2.8; **XbaI**: WT = 7.8, mutants = 4.1. MW: DIG-labeled DNA molecular weight marker III (Roche, Indianapolis, IN). 872 bp fragment of *Sau3AI*-digested *frh* deletion plasmid (pGK4, Table 3.1) was used as probe.

Figure 3.5 Verification of Δvht in $\Delta vht \Delta frh$ by Southern hybridization. Predicted bands (kb): **Asel**: WT (WWM85) = 7.4, mutant (M) = 3.1; **HindIII**: WT = 5.9, mutant = 3.9; **PstI**: WT = 2.2 and 2, mutant = 2 and 1.4; **XhoI**: WT = 10.7, mutant = 8.5. MW: DIG-labeled DNA molecular weight marker III (Roche, Indianapolis, IN). 831 bp fragment of *KpnI*-digested *vht* deletion plasmid (pGK5, Table 3.1) was used as probe.

3.3.4 Construction of tetracycline-regulated *vht* and *mcr* mutants

In a previous study (18), the *PmcrB* promoter of *M. barkeri* was modified to include binding sites for the TetR protein (*tetO*). Three promoters with variable placement of *tetO* were constructed, designated *PmcrB(tetO1)*, *PmcrB(tetO3)* and *PmcrB(tetO4)*, to allow expression of the desired gene at different levels. Thus, the *PmcrB(tetO1)* promoter is expressed at the highest level, whereas, expression of *PmcrB(tetO3)* is lowest. To render expression of hybrid *PmcrB(tetO)* promoters (18) tetracycline-dependent, *M. barkeri* Fusaro strains containing a *tetR* gene were constructed. To accomplish this, plasmids harboring *PmcrB-tetR-φC31int-attB* (pGK1) or *PmcrB-tetR-φC31int-attP* (pGK2) were inserted into the *hpt* locus using the markerless method of genetic exchange (42) to obtain WWM154 or WWM155, respectively (Table 3.3). These strains were then confirmed by DNA hybridization (Figure 3.6). To enable expression of *M. barkeri* genes from the hybrid promoters, each one of these *PmcrB(tetO)* promoter was cloned into a vector containing selectable (*pac*) & counter-selectable (*hpt*) markers and a copy of *PmcrB* driven *tetR* to give rise to a series of plasmids. This includes pGK50A/B & pGK25 with *PmcrB(tetO1)*, pGK51A/B & pGK26 with *PmcrB(tetO3)* and pGK52A/B and pGK27 with *PmcrB(tetO4)* (Table 3.1). Subsequently, in each of these vectors, the upstream and coding regions of *vht* were cloned using the *NcoI*/*Apal* and *NdeI*/*SpeI* sites, respectively. The resulting plasmids were then digested with *NcoI*/*SpeI* to give a 7 kb fragment that was transformed into WWM154 or WWM155 (Table 3.3). The transformants were selected using methanol plus H₂/CO₂ in the presence of puromycin and Tc.

To ensure that the native promoter of *vht* does not interfere with *PmcrB(tetO)* in *vht* expression, 382 bp upstream of *vht* were deleted in the Tc-regulated *vht*

Figure 3.6 Verification of *PmcrB-tetR-φC31int-attB* insertion at *hpt* locus in WWM154 and WWM155 by Southern hybridization. Predicted bands (kb): **EcoRV**: WT (*M. barkeri* Fusaro) = 2, WWM154 (1 and 2) = 4.2; **BglII**: WT = 3.2, WWM154 and WWM155 (3 and 4) = 5.4; **PvuII**: WT = 4.9, WWM155 = 7.1. MW: DIG-labeled DNA molecular weight marker III (Roche, Indianapolis, IN). 700 bp PCR-product of pGK1 amplified with primers tetRsouthernfor and tetRsouthernrev was used as probe (Tables 3.1 and 3.2).

strains, still keeping intact 1038 bp for the expression of *hyp* operon (Figure 3.2).

Based on sequence homology to *M. mazei vht* promoter (16), the *M. barkeri vht* promoter is presumed to be located within 140 bp upstream of *vht* (12) and thus, the Tc-regulated *vht* strains are probably deleted of the native *vht* promoter.

Further studies were performed using the strain obtained from transformation with the pGK51A derivative, which contains *PmcrB(tetO3)* (*P_{tet}vht*, WWM157). This strain was confirmed by sequencing the PCR amplified *vht* promoter of WWM157

and using DNA hybridization (Figure 3.7). The *mcr* upstream and coding regions were cloned in *PmcrB(tetO1)*-containing pGK50A/B, using *Apal* and *NdeI/SpeI* sites, respectively (Table 3.1). The translational start site of *mcr* was modified

Figure 3.7 Verification of $P_{tet}vht$ by Southern hybridization. Predicted bands (kb): **BglIII**: WT (WWM154) = 5.1, $P_{tet}vht$ (1, 2, 3 and 4) = 7.9; **XhoI**: WT = 10.7, $P_{tet}vht$ = 6.8; **HincII**: WT = 5.7, $P_{tet}vht$ = 4.9. MW: DIG-labeled DNA molecular weight marker III (Roche, Indianapolis, IN). 481-bp fragment of *EcoRI*-digested pGK60A (Table 3.1) was used as probe.

from GTG to ATG for cloning purposes. The *SpeI*-digested pGK50B derivative (pGK90) was then used to obtain the Tc-regulated *mcr* strain ($P_{tet}mcr$, WWM235). This strain was confirmed by sequencing the PCR amplified *mcr* promoter of WWM235. Surprisingly, the modified ATG start codon of *mcr* was mutated back to its native GTG in each of the three clones sequenced. As in case of $P_{tet}vht$ strain, 149 bp upstream of *mcr* were deleted to remove the native *mcr* promoter in $P_{tet}mcr$ strain (18).

3.3.5 Determination of growth characteristics

For growth rate determinations, cultures were grown using methanol (Δhpt , Δvhx and $\Delta vht \Delta frh$) or methanol plus H_2/CO_2 (Δfrh) to mid-log phase (optical density at 600 nm [OD₆₀₀] ca. 0.5). Approximately 3% inoculum of the culture (or 10%, in case of acetate) was then transferred to fresh medium in four replicates and incubated at 37° C. Growth was quantified by measuring OD₆₀₀. Generation times were calculated during exponential growth phase and lag phase was defined as the time required to achieve half-maximal OD₆₀₀. For growth curve experiments with and without Tc, strains were adapted to methanol and methanol plus H_2/CO_2 for 30 generations, and H_2/CO_2 and acetate for 15 generations in the presence of Tc. The adapted cultures were grown till mid-log phase (OD₆₀₀ ca. 0.5 for methanol and methanol plus H_2/CO_2 and OD₆₀₀ ca. 0.25 for H_2/CO_2 and acetate) and then serially diluted to 10^{-5} (methanol and methanol plus H_2/CO_2) or 10^{-4} (H_2/CO_2 and acetate) with and without Tc in four replicates. Growth was then monitored at OD₆₀₀.

3.3.6 Cell suspension experiments

Cells grown on methanol (Δhpt , Δvhx and $\Delta vht \Delta frh$) or methanol plus H_2/CO_2 (Δfrh) were collected in late exponential phase (OD₆₀₀= 0.6-0.7) by centrifugation at 5,000 x g for 15 minutes at 4 °C. They were then washed once with anaerobic HS PIPES buffer, 50 mM PIPES (pH 6.8), 400 mM NaCl, 13 mM KCl, 54 mM MgCl₂, 2 mM CaCl₂, 2.8 mM cysteine, 0.4 mM Na₂S and resuspended in the same buffer to a final concentration of 10^9 cells/ml. Cells

were counted visually using the Petroff-Hausser counting chamber (Hausser Scientific, PA). All assay mixtures contained 2 ml of the suspension and were conducted under strictly anaerobic conditions in 25 ml Balch tubes sealed with butyl rubber stoppers. Puromycin (20 μ g/ml) was added to prevent protein synthesis and as indicated, the assay mixture contained 250 mM methanol under a headspace of N₂, H₂ or H₂/CO₂ (80/20%) at 250 kPa over the ambient pressure. Cells were held on ice until use and assays were started by transferring tubes to 37°C. For rate determination, gas phase samples were withdrawn at various time points and assayed for CH₄ by gas chromatography at 225°C in a Hewlett Packard gas chromatograph (5890 Series II) equipped with a flame ionization detector. The column used was of stainless steel filled with 80/120 CarbopackTM B/3% SPTM-1500 (Supelco, Bellefonte, PA) with helium as the carrier gas. For total CH₄ and CO₂ production, assays were incubated at 37°C for 36 hours and then gas phase samples were withdrawn. These samples were analyzed by GC at 225°C in a Hewlett Packard gas chromatograph (5890 Series II) equipped with a thermal conductivity detector. A stainless steel 60/80 Carboxen-1000 column (Supelco, Bellefonte, PA) with helium as the carrier gas was used. Total cell protein was determined using the Bradford method (7) after 1 ml of the cells was lysed by resuspending it in ddH₂O with 1 μ g/ml RNase and DNase.

3.3.7 Measurement of H₂, CH₄ and OD₆₀₀ during methylotrophic growth

WWM154, P_{tet}vht (grown in presence of Tc), Δ frh and Δ vht Δ frh strains were grown using methanol till mid-log phase (OD₆₀₀ c. 0.5) and then 1 ml (WWM154 and P_{tet}vht) or 5ml (Δ frh and Δ vht Δ frh) were inoculated into 100 ml HS-methanol in a 500 ml serum bottle. For P_{tet}vht strain, the culture was washed once prior to inoculation into media with or without Tc. To measure H₂ and CH₄, ca. 1 ml or 2 ml headspace samples were withdrawn aseptically from the culture at various time points with a syringe that had been flushed with sterile, anaerobic N₂. The gas samples were then diluted into 70 ml helium. A gas-tight syringe flushed with helium was subsequently used to withdraw 3 ml of the diluted sample, which was then injected into an SRI gas chromatograph, equipped with a reduction gas detector (RGD) and a thermal conductivity detector (TCD) at 52°C. The RGD column was a three feet long 13X molecule sieve, whereas the TCD column was six feet HayeSep D. RGD was used to detect H₂ by peak height and TCD for CH₄ by peak area. Helium was used as the carrier gas. OD₆₀₀ was also measured during the growth curve.

3.4 RESULTS

3.4.1 Vhx is dispensable whereas Vht is essential for growth of *M. barkeri*

As described above, Frh preferentially channels electrons from F₄₂₀H₂ to H₂ during methylotrophic growth of *M. barkeri* (Figure 3.1). The H₂ is then presumably taken up by MP-dependent hydrogenase and fed into the H₂:heterodisulfide oxidoreductase system for reduction of CoM-S-S-CoB (22).

Thus, we predicted that deletion of MP-dependent hydrogenase from the organism should affect its growth using methanol. To test this *in vivo*, we attempted to delete the operons encoding MP-dependent hydrogenases in *M. barkeri*, *vhxGAC* and *vhtGACD*.

The *vhxGAC* operon (Figure 3.2) was deleted from the chromosome of *M. barkeri* Fusaro using methanol plus H₂/CO₂ as the growth substrate (Table 3.3). The phenotype exhibited by the Δ *vhx* mutant, in terms of growth characteristics and CH₄ and CO₂ production in resting cell suspensions, is similar to the isogenic parental strain on all substrates (Tables 3.4, 3.5 & 3.6). Therefore, Vhx is not required for growth of *M. barkeri* under the conditions tested; however, this does not rule out the possibility that it may still encode a functional hydrogenase.

We tried to delete the *vhtGACD* operon (Figure 3.2) numerous times from the chromosome of *M. barkeri* Fusaro by the homologous gene replacement method (53) using methanol or methanol plus H₂/CO₂ as growth substrates, with and without media supplementation (yeast extract, casamino acids, pyruvate and acetate). However, no puromycin-resistant *vht* mutant colonies were obtained, implying that loss of Vht might be deleterious to the cell under the tested conditions. As an alternative strategy, we also employed the markerless method of genetic exchange (42) to delete *vht*. In this selection/countersélection method, if there is no selective pressure for or against the mutant allele, then 50% of the segregants are expected to be mutant strains. However, in case the mutant strain has a growth defect, the wild-type strain would outgrow it, thereby reducing the probability of obtaining segregants with the mutant allele. All the

101 8-ADP-resistant segregant colonies screened for *vht* deletion were wild-type, which is consistent with the idea that *vht* might be essential for growth of *M. barkeri* under the conditions examined.

3.4.2 Validation of the tetracycline-regulated system used to test gene essentiality

To test this system, the expression of an essential gene in *M. barkeri* encoding the methyl-CoM reductase, *mcr* (43), was rendered Tc-dependent in the $P_{tet}mcr$ strain (WWM235, Table 3.3). Expression of native *mcr* promoter is closest to that of $P_{mcrB}(tetO1)$, thus, this promoter was used to express *mcr* in $P_{tet}mcr$ strain. This strain grew well on solid medium with methanol as a growth substrate, so long as tetracycline was included. However, no growth was observed in the absence of tetracycline (Figure 3.8). Similar results were obtained in liquid media containing methanol, methanol plus H₂/CO₂, H₂/CO₂ or

acetate as growth substrates, indicates that Mcr is essential for growth on all methanogenic substrates tested (Figure 3.9). This validates the Tc-regulated gene essentiality system.

Figure 3.8 Growth of tetracycline-regulated *mcr* ($P_{tet}mcr$) and *vht* ($P_{tet}vht$) mutants of *M. barkeri* on plates containing methanol. WWM154 (parent strain, Table 3.3), $P_{tet}mcr$ and $P_{tet}vht$ strains were streaked on methanol plates with and without tetracycline (Tc). Unlike WWM154, which was able to grow in the presence and absence of Tc, $P_{tet}mcr$ and $P_{tet}vht$ strains could grow only in the presence of Tc.

3.4.3 Isolation of an *M. barkeri* conditional *vht* mutant

Due to our inability to isolate a *vht* deletion mutant, a Tc-regulated *vht* conditional mutant, hereafter referred to as $P_{tet}vht$ (WWM157), was constructed (Table 3.3) (18). The native promoter of *vht* is expressed at levels similar to $P_{mcrB(tetO3)}$ (16, 18), therefore, this promoter was used to drive *vht* expression in $P_{tet}vht$. To check if Vht is essential for growth using methanol, the $P_{tet}vht$ strain

was streaked on this substrate with and without Tc (Figure 3.8). Unlike the parental strain that grew under both conditions, the $P_{tet}vht$ strain could only grow

Figure 3.9 Growth of tetracycline-regulated *mcr* ($P_{tet}mcr$) and *vht* ($P_{tet}vht$) mutants of *M. barkeri* on methanol plus H_2/CO_2 . WWM154 (parent strain, Table 3.3), $P_{tet}mcr$ and $P_{tet}vht$ strains were grown on methanol plus H_2/CO_2 with and without tetracycline (Tc) as described in Materials and Methods. Growth was monitored in triplicate cultures at OD_{600} . Unlike WWM154, which was able to grow in the presence and absence of Tc, $P_{tet}mcr$ and $P_{tet}vht$ could grow only in the presence of Tc. Similar growth curve experiments were also performed on methanol, H_2/CO_2 and acetate. Growth was tested at 10^{-5} dilution on methanol and methanol plus H_2/CO_2 , and at a dilution of 10^{-4} on H_2/CO_2 and acetate. At these dilutions, the concentration of residual Tc contributed by the inoculum is less than that required for induction of the *PmcrB(tetO)* promoter ($1 \mu g/ml$) (18) and there are *ca.* 1000 cells present in the inoculum. On each of the methanogenic substrate tested, both the Tc-dependent strains, $P_{tet}mcr$ and $P_{tet}vht$, could not grow without tetracycline for more than six months. This proves their essentiality on the substrates tested. Cultures, WWM154 with Tc (dark green squares), WWM154 without Tc (lime squares), $P_{tet}mcr$ with Tc (red triangles), $P_{tet}mcr$ without Tc (pink triangles), $P_{tet}vht$ with Tc (dark blue circles), $P_{tet}vht$ without Tc (turquoise circles).

when Tc was present in the medium. Similar results were obtained in liquid media containing methanol, methanol plus H_2/CO_2 , H_2/CO_2 or acetate as growth substrates (Figure 3.9). This proves that Vht is essential for growth of wild-type

M. barkeri on all methanogenic substrates tested. Vhx is present in the $P_{tet}vht$ strain; however, it is not able to substitute for the role of Vht in growth of *M. barkeri*, indicating that Vhx is non-functional under the conditions tested.

3.4.4 Hydrogen accumulation in the tetracycline-regulated *vht* mutant inhibits methylotrophic growth

If Frh and Vht mediate electron transfer from $F_{420}H_2$ to MP via H_2 during growth on methanol, then absence of Vht from the cell should result in H_2 accumulation (Figure 3.1). To test this, H_2 production was measured as a function of growth and amount of CH_4 production in cultures of wild-type (WWM154), Δfrh and $P_{tet}vht$ strains. The $P_{tet}vht$ strain was grown with and without Tc. In the presence of Tc, *vht* is expressed, enabling $P_{tet}vht$ strain to grow like the parental strain. However, *vht* is not expressed in the absence of Tc. Nevertheless, growth occurs to a level of ca. 50% of wild-type, which we believe is due to dilution of existing Vht protein in the cells of the inoculum. The parental strain showed a gradual increase in H_2 concentration as CH_4 production and growth ensued (Figure 3.10). Once CH_4 production ceased (ca. 26 kPa), the culture entered stationary phase and the concentration of H_2 reached an equilibrium value of ca. 18 Pa. When inoculated into HS-methanol medium with Tc, growth of $P_{tet}vht$ strain was indistinguishable from the parental strain. However, when inoculated into the same medium without Tc, the $P_{tet}vht$ strain accumulated H_2 to a level six times higher than the parental strain. CH_4 production ceased and the $P_{tet}vht$ culture began to lyse, as H_2 concentration

increased to ca. 40 Pa. H₂ accumulation continued further with no growth and a considerable decrease in rate of CH₄ production. Thus, absence of Vht from the

Figure 3.10 (cont.)

Figure 3.10 Hydrogen, methane and growth production in methanol-growing *M. barkeri* cultures. In Panel A, H₂ production was measured as a function of time in methanol-growing cultures of, WWM85 (red diamonds, *M. barkeri* Fusaro parent strain used to construct mutants, Table 3.3), tetracycline-regulated *vht* mutant (*P_{tet}vht*) with tetracycline (dark blue squares), *P_{tet}vht* without tetracycline (turquoise triangles), Δfrh mutant (orange stars), $\Delta vht \Delta frh$ (lime circles) double mutant. The *P_{tet}vht* strain accumulated H₂ to 107 Pa as opposed to the parent strain that produced only 18 Pa H₂. For each time point in the experiment, corresponding measurements were also made for methane production (Panel B) and growth (Panel C). Growth was measured by monitoring optical density at 600 nm (OD₆₀₀). Measurements were done in triplicates as described in Materials and Methods. H₂ accumulation causes cessation of CH₄ production and cell lysis in the *P_{tet}vht* strain.

cell leads to H₂ accumulation, which is consistent with our prediction that Vht consumes H₂ produced during methylotrophic growth. In contrast to the isogenic parental strain, the Δfrh mutant did not produce H₂ as CH₄ production and growth ensued. The H₂ concentration barely increased from 2 Pa to a final value of ca. 8 Pa, as opposed to 18 Pa in the parental strain. This suggests that Frh might be one of the sources of H₂ in the parental strain.

3.4.5 Vht is dispensable in an *M. barkeri frh* mutant background

As discussed in the previous section, H₂ accumulation in P_{tet}*vht* strain is accompanied by growth inhibition. Also, the Frh hydrogenase produces H₂ during methylotrophic growth. Therefore, we predicted that a Δvht mutant would be viable in a Δfrh markerless mutant background (42). While multiple attempts to isolate the single Δvht mutant had failed, the $\Delta vht \Delta frh$ double mutant was isolated in the first attempt, using methanol as the growth substrate (Table 3.3). Like the single Δfrh mutant, the $\Delta vht \Delta frh$ double mutant is unable to grow using H₂/CO₂ (Tables 3.4, 3.5 & 3.6). The double mutant grows slower using methanol relative to the parental strain, with a *ca.* 34% increase in doubling time and 50% reduction in rate of CH₄ production in resting cell suspensions. However, the ratio of CO₂ to CH₄ produced in resting cell suspensions on methanol is 1:3, which is identical to that of the parental strain. The single Δfrh mutant exhibits a similar phenotype on methanol. The $\Delta vht \Delta frh$ double mutant has a five-fold slower growth rate, *ca.* 50% reduction in growth yield, and a longer lag phase than the parental strain on methanol plus H₂/CO₂. The rate of CH₄ production and the total CH₄ produced in resting cell suspensions are also *ca.* six-times and three-times lower, respectively, relative to the parental strain on this substrate. The $\Delta vht \Delta frh$ double mutant does not produce CO₂ in resting cell suspensions on methanol plus H₂/CO₂. In contrast to the single Δfrh mutant, the $\Delta vht \Delta frh$ double mutant fails to grow on acetate. H₂ production was also measured in methanol-growing cultures of $\Delta vht \Delta frh$ double mutant (Figure 3.10). Unlike the single Δfrh mutant that produces only 8 Pa of H₂, the $\Delta vht \Delta frh$ double mutant accumulates H₂ to

about 22 Pa, indicating an alternate source of hydrogen production apart from Frh.

3.5 DISCUSSION

H₂-cycling, as a mechanism of energy conservation, has been controversial since its proposal by Odom and Peck in 1981 (36). However, our results suggest that H₂ accumulates when cycling is disrupted genetically in *M. barkeri*. The cycling apparently involves Frh hydrogenase that produces H₂ from F₄₂₀H₂, and Vht hydrogenase that consumes this H₂ (Figure 3.1). Consistent with this idea, our data show that Vht is essential for growth of *M. barkeri* on all substrates, including methanol. Furthermore, a tetracycline-regulated conditional *vht* mutant is shown to accumulate H₂ to a six-times higher level than the parental strain on methanol as the growth substrate, confirming involvement of Vht in H₂ consumption. In contrast, our results suggest that the Δfrh mutant produces negligible amount of H₂ on methanol, which is consistent with the role of Frh as the H₂-evolving hydrogenase. Based on these results, we propose a model of energy conservation, in which, Frh couples F₄₂₀H₂ oxidation to H₂ production using two protons from the cytoplasm. Subsequently, the H₂ diffuses to the active site of Vht in the periplasm, where it is oxidized to release two protons. Thus, this H₂-cycling mechanism creates a trans-membrane proton gradient that can be used to form ATP by the ATP synthase (34).

In Chapter 2 (22), I demonstrated that *M. barkeri* uses the H₂-cycling pathway preferentially, but not exclusively, because Δfrh mutants grow on

methanol, using Fpo. It was postulated that the H₂-dependent route is preferred due to kinetic advantage of Frh over Fpo. This is consistent with the observation that Fpo is unable to compete with Frh to prevent loss of electrons from F₄₂₀H₂ in the form of H₂ gas, when the H₂-uptake hydrogenase, Vht, is absent. The H₂ escapes from the cell, because it is detected in H₂ measurements with the conditional *vht* mutant. This is probably the reason for the inability of this mutant to grow on methanol. Consistent with this idea, deletion of *frh* allowed isolation of the Δvht mutant in *M. barkeri*.

The $\Delta vht \Delta frh$ double mutant is still capable of some H₂ production. The source of this H₂ is most likely Ech, as it is the only functional hydrogenase encoded by the mutant cell. Fre and Vhx are non-functional in the $\Delta vht \Delta frh$ double mutant because they are unable to substitute for the role of Frh and Vht, respectively, on any methanogenic substrate tested (16, 22). During methylotrophic growth, Ech has been proposed to transfer electrons from Fd_{red}, produced during the methyl oxidative pathway, to H₂ (30, 31). The H₂ can then be fed into the H₂:heterodisulfide oxidoreductase system for reduction of the CoM-S-S-CoB heterodisulfide (11). In other words, Ech and Vht may also engage in H₂-cycling because the active site of Ech is located in cytoplasm (23), whereas that of Vht is in the periplasm (Figure 3.1). In the absence of Vht and Frh, H₂ produced by Ech accumulates. Although this causes a slight reduction in CH₄ production (ca. 4 kPa), growth inhibition does not occur. This is because *M. barkeri* also contains an as yet unidentified Fd_{red} oxidoreductase that can transfer reducing equivalents from Fd_{red} via a H₂-independent pathway (31). Our data

indicate that this Fd_{red} oxidoreductase is efficient enough to prevent a complete loss of electrons from Fd_{red} as H_2 . Unlike $\Delta vht \Delta frh$ double mutant, the single Δfrh mutant accumulates only negligible quantities of H_2 . This implies that Vht present in the single mutant consumes H_2 produced by Ech. Although it is uncertain which Fd_{red} oxidation pathway is used preferentially, our evidence suggests involvement of Ech in H_2 -cycling. This is significant because, Ech and Vht are also believed to conserve energy via H_2 -cycling during acetate metabolism (30, 31).

M. barkeri probably evolved branched electron transport chains for energy conservation to adapt to different environmental conditions. In the environment, methanogens have to compete for H_2 with other micro-organisms, like denitrifiers, sulfate-reducing bacteria, iron-reducing bacteria and manganese-reducers. This is because, these organisms have a higher affinity for H_2 than methanogens. *M. barkeri* occurs as large multi-cellular aggregates in its freshwater habitat (26). Therefore, existence of dual electron transport system might confer it the flexibility of using the faster H_2 -dependent pathways when present within the aggregates, where H_2 gas would not be lost to competing H_2 -consumers in its environment (17). However, cells at the periphery of the aggregate might employ H_2 -independent pathways to prevent such losses. *M. barkeri* has been shown to lose H_2 to its environment under low *in situ* H_2 concentrations or during syntrophic associations with sulfate-reducing bacteria, (15, 41, 48). In such cases, H_2 -independent pathways would be undoubtedly beneficial, as H_2 production via the methyl oxidative pathway is not known to

conserve energy (11). A recent model in the sulfate reducer, *Desulfovibrio vulgaris*, proposes similar dual electron transport system for rapid adaptation to availability of various electron acceptors and donors in the environment (35).

M. barkeri might also utilize H₂-independent pathways under certain environmental conditions, when hydrogenases are inactive. For example, Ni-deprivation might result in hydrogenase-deficiency and subsequent use of H₂-independent pathways. Such Ni-dependent regulation is seen in a methanogen that belongs to the order *Methanobacteriales*, *Methanobacterium thermoautotrophicum*. This regulation involves [NiFe] hydrogenase Frh and Ni-free enzymes Hmd (H₂-forming methylene-tetrahydromethanopterin dehydrogenase and Mtd (F₄₂₀-dependent methylene-tetrahydromethanopterin dehydrogenase) (1).

Unlike *M. barkeri* that preferably uses H₂-cycling, other methylophilic species like *M. acetivorans* (16, 17), *Methanlobus tindarius* (19, 45) and *Methanococcoides burtonii* (44), probably employ H₂-independent oxidoreductase systems for energy conservation, because they do not encode functional hydrogenases. This might be advantageous to these marine species that exist as single cells in their habitat (46) and are therefore more prone to lose H₂ gas to competing micro-organisms in their environment. Also, this could be the reason why these species forego H₂-dependent electron transport pathways. In contrast, the fresh-water *M. mazei* might be able to use H₂-cycling within its cell aggregates, as it has functional Frh, Vht, Ech and Fpo enzymes (14).

Although several studies in the past have proposed the occurrence of H₂-cycling in methanogens (22, 24, 25), this study has provided direct experimental observation in *M. barkeri*. This is significant because, several anaerobic organisms possess the potential to use H₂-cycling for energy conservation. For instance, after its initial proposal in sulfate-reducing bacteria (36), H₂-cycling was also suggested to occur in the acetogen *Acetobacterium woodii* (37) and in the Fe (III) respiring *Geobacter sulfurreducens* (8, 29). Thus, H₂-cycling could be a general phenomenon in an anaerobic microbial community.

The deletion analysis of *vht* provides insight into the metabolism of various methanogenic substrates by *M. barkeri*. In the CO₂ reduction pathway, Vht is proposed to provide MPH₂ for methyl group reduction (47). Consistent with this role, the *P_{tet}vht* and $\Delta vht \Delta frh$ mutants are not able to grow using H₂/CO₂. During aceticlastic growth, Vht consumes H₂ produced by Ech, in a presumed H₂-cycling mechanism (30, 31). This is supported by the inability of *P_{tet}vht* mutant to grow using acetate. Furthermore, unlike the single Δfrh mutant, $\Delta vht \Delta frh$ double mutant fails to grow using this substrate, suggesting involvement of Vht in aceticlastic growth. In the methyl respiration pathway (21), methyl group of methanol is reduced to CH₄ using electrons derived from the oxidation of H₂ by Vht. However, the $\Delta vht \Delta frh$ double mutant can grow via this pathway, presumably using Ech. This is because, Ech is the only functional hydrogenase present in this double mutant. Therefore, it must be responsible for oxidizing H₂ to provide Fd_{red} for methyl group reduction. Surprisingly, the conditional *P_{tet}vht* mutant is unable to grow using methanol plus H₂/CO₂. It is unclear why this

mutant fails to utilize the Ech-dependent pathway for growth via the methyl respiration pathway. It is apparent that presence of Frh, prevents Fd_{red} -dependent respiration in the $P_{tet}vht$ mutant, however, this needs to be tested.

Finally, Vhx is not able to substitute for the role of Vht on any methanogenic substrate. This may be due to low expression of *vhx*, absence of post-translational processing, mutations in structural or catalytic residues, or some combination of these (16). Thus, the role of Vhx, which is conserved in all the three *Methanosarcina* species, is still unclear.

CHAPTER 4

CONVERSION OF *METHANOSARCINA BARKERI* INTO A NON-HYDROGENOTROPHIC *METHANOSARCINA ACETIVORANS*-LIKE SPECIES REVEALS FEATURES OF ITS BRANCHED HYDROGEN-DEPENDENT AND -INDEPENDENT ELECTRON TRANSPORT PATHWAYS

4.1 ABSTRACT

The methanogen *Methanosarcina barkeri* encodes three kinds of [NiFe] hydrogenases; ferredoxin (Fd_{ox})-dependent Ech, F₄₂₀-dependent Frh and methanophenazine (MP)-dependent Vht. Although these hydrogenases are directly involved in H₂ metabolism when the organism is grown using H₂/CO₂ or methanol plus H₂/CO₂, they also play an important role in the methylotrophic and acetoclastic pathways, in which H₂ is produced as an intermediate, in a presumed “H₂-cycling” pathway for energy conservation. To further dissect the roles of these hydrogenases in *M. barkeri* physiology, we constructed a series of hydrogenase deletion mutants in various permutations and combinations, including a mutant that is devoid of all three types of hydrogenases. Our data show that each of the three types of hydrogenases is needed for growth via the CO₂ reduction pathway. In contrast, none of the hydrogenases is essential during methylotrophic growth, indicating the presence of H₂-independent electron transport chains, which are able to support wild-type growth yields. While the reduced F₄₂₀ (F₄₂₀H₂):heterodisulfide pathway has been identified in a previous study to involve Fpo, the components of the reduced Fd_{ox} (Fd_{red}):heterodisulfide pathway remain unknown. However, our study demonstrates that this unidentified pathway is as efficient as H₂-cycling in supporting methylotrophic

growth. Additionally, it allows growth via the methyl respiration pathway when Fd_{red} is made available by the action of Ech. Surprisingly, the Fd_{red} :heterodisulfide pathway is insufficient for acetoclastic growth for unknown reasons. The data presented here also suggest that Ech and/or Frh exert inhibitory effects on the methyl oxidative pathway by catalyzing conversion of H_2 to Fd_{red} and F_{420}H_2 , respectively. Finally, this study provides evidence for involvement of Hyp proteins in maturation of at least one of the [NiFe] hydrogenases, Ech. This work highlights the similarities and differences between H_2 -independent electron transport chains of the hydrogenotroph *M. barkeri* and the non-hydrogenotroph *Methanosarcina acetivorans*.

4.2 INTRODUCTION

Hydrogenases play an important role in microbial metabolism by virtue of their ability to catalyze the reversible oxidation of molecular hydrogen (H_2) (48). In methanogenic Archaea, H_2 is primarily used to reduce CO_2 to methane (CH_4) (46). However, some methanogens like *Methanosphaera* (29, 38) and *Methanosarcina barkeri* (20), can also utilize H_2 for reduction of methylated C-1 compounds like methanol to CH_4 . *M. barkeri* also produces H_2 , when grown using methanol alone via the methylotrophic pathway (25, 30). It is postulated that acetoclastic growth involves the obligate production of H_2 as well, in *M. barkeri* (25, 30, 36) and *Methanosarcina mazei* (51). Thus, hydrogenases seem to be important for growth of methanogenic species like *M. barkeri* on a range of substrates. *M. barkeri* encodes three types of [NiFe] hydrogenases that differ

Figure 4.1 (cont.)

or H_2 to CoM-S-S-CoB. The electrochemical gradient generated is coupled to ATP synthesis via an A-type ATPase. There is evidence to suggest that Ech/Vht may also conserve energy via the H_2 -cycling mechanism. In this, Ech presumably couples the exergonic oxidation of Fd_{red} to H_2 formation, concomitantly pumping an unknown number of protons outside the cell. The proton-motive force is likely used for the transfer of methyl group from methyl-CoM to tetrahydrosarcinapterin. However, the H_2 may diffuse out to Vht and enter the H_2 :heterodisulfide oxidoreductase system for energy conservation. The organism also contains a soluble Hdr, HdrA1B1C1, which has been proposed to transfer electrons from Fd_{red} to CoM-S-S-CoB in *Methanosarcina acetivorans*. This transfer is mediated in a one-step reaction or using an electron bifurcation mechanism, where for every CoM-S-S-CoB reduced, a molecule of coenzyme F_{420} also undergoes reduction. Scalar or vectorial protons translocated across the cell membrane are highlighted in red. Abbreviations; Ech, Fd-dependent hydrogenase; Frh, F_{420} -reducing hydrogenase; Fpo, $F_{420}H_2$:phenazine oxidoreductase; Vht, methanophenazine-dependent hydrogenase; Hdr, heterodisulfide reductase; CoM-SH, coenzyme M; CoB-SH, coenzyme B; CoM-S-S-CoB, mixed disulfide of CoM-SH and CoB-SH; MP/MPH₂, oxidized and reduced methanophenazine; Fd_{ox}/Fd_{red} , oxidized and reduced ferredoxin; $F_{420}/F_{420}H_2$, oxidized and reduced Factor 420; FAD, flavin adenine dinucleotide; [FeS], iron-sulfur cluster; [NiFe], bimetallic catalytic center; *Cytb₂*, cytochrome *b₂*.

Three distinct physiological roles of this hydrogenase were revealed in *M. barkeri* by mutational analysis of the Ech-encoding operon, *echABCDEFG* (Figure 4.2) (36). Firstly, in the CO_2 reduction pathway, Fd_{red} generated by Ech acts as an electron donor for reduction of CO_2 to the formyl level. Secondly, Fd_{red} is also needed for biosynthesis in the CO_2 reduction and methyl-respiration pathways. Thirdly, Ech is required during acetoclastic growth as well. Here, it most likely transfers electrons from Fd_{red} , which is produced from oxidation of carbonyl group of acetate to CO_2 , to H_2 in an energy-conserving reaction. Subsequently, this cytoplasmically produced H_2 can diffuse out of the cell to the active site of the MP-dependent hydrogenase Vht, where it is oxidized to generate electrons and protons (35, 36). The electrons are fed into the electron transport chain, H_2 :heterodisulfide oxidoreductase system (12), that terminates with the reduction of the heterodisulfide (CoM-S-S-CoB) of coenzyme M (CoM-SH) and coenzyme B (CoB-SH). However, the consumption and production of protons by Ech and

Vht in the cytoplasm and periplasm, respectively, creates an energy-conserving proton gradient via the H₂-cycling mechanism (Figure 4.1) (41). A similar role of Ech has also been proposed in the methylotrophic pathway (25, 35, 36), in which Fd_{red} produced by formyl group oxidation might be converted into H₂ by this

Figure 4.2 Genomic organization of operons encoding ferredoxin-dependent hydrogenase (Ech) in *Methanosarcina* species. Ech is encoded by the 6-gene operon (*echABCDEF*) in *M. barkeri* and *M. mazei*. *M. acetivorans*, however, is missing the *ech* operon.

hydrogenase. However, the Δech mutant of *M. barkeri* is capable of transferring electrons from Fd_{red} to the heterodisulfide in an Ech-independent manner, suggesting the presence of an alternate H₂-independent pathway involving an unidentified Fd_{red} oxidoreductase (36). Deletion analysis of *ech* operon (Figure 4.2) in the closely related *M. mazei* species, supports the proposed function of Ech in the acetoclastic and methylotrophic pathways (51). In addition, this study

provides biochemical evidence for the presence of a Fd_{red} oxidoreductase in *M. mazei*, which is capable of mediating electron transfer from Fd_{red} to the heterodisulfide in an Ech-independent manner. This is in support of the presence of such an enzyme in *M. barkeri* as well. Interestingly, *M. acetivorans* lacks the *ech* operon (18). Thus, it relies exclusively on H_2 -independent putative Fd_{red} oxidoreductases, including the Na^+ -pumping $\text{Fd}_{\text{red}}:\text{MP}$ oxidoreductase (Rnf) (28) and/or the soluble heterodisulfide reductase (HdrA1B1C1) (9), while growing on acetate and methanol as substrates. Although Rnf is not present in *M. barkeri* (31) and *M. mazei* (14), both species contain operons encoding HdrA1B1C1 in their genomes. In conclusion, Fd_{red} -dependent H_2 -independent pathways seem to be a common feature of all *Methanosarcina* species.

The F_{420} -dependent hydrogenase (Frh) has also been purified from *M. barkeri* (16, 37). It catalyzes the reversible reduction of coenzyme F_{420} with H_2 (Figure 4.1). Reduced F_{420} (F_{420}H_2) serves as an electron donor for reduction of methenyl and methylene groups in the CO_2 reduction pathway (37, 46). Consistent with this function, the deletion mutant of the operon encoding Frh, *frhADGB*, in *M. barkeri* is unable to grow on H_2/CO_2 as a substrate (24). The Δfrh mutant also shows a severe growth defect on methanol. Therefore, Frh was proposed to transfer electrons from F_{420}H_2 , produced from methyl and methylene group oxidation, to H_2 in the methylotrophic pathway (37). As shown in chapter 3 (25), the H_2 enters the H_2 :heterodisulfide oxidoreductase system via the action of Vht (Figure 4.1). Because Frh is located within the cytoplasm, whereas Vht is periplasmic, the production and subsequent oxidation of H_2 by these two

hydrogenases conserves energy via the H₂-cycling mechanism (25). Although H₂-cycling is the preferential (faster) mode of electron transfer from F₄₂₀H₂ to the heterodisulfide, the F₄₂₀H₂ dehydrogenase (Fpo) is able to perform this transfer in a H₂-independent way by employing the F₄₂₀H₂:heterodisulfide oxidoreductase system (Figure 4.1) (24). In this system (12), electrons are initially channeled from F₄₂₀H₂ to MP via Fpo. Subsequently, as in the H₂:heterodisulfide system, reduced MP (MPH₂) is used by the membrane-bound heterodisulfide reductase (HdrED) to reduce the CoM-S-S-CoB heterodisulfide. *M. mazei* (14) and *M. acetivorans* (18) also contain operons encoding Frh, Vht and Fpo. While *M. mazei* might be able to employ both the Frh/Vht and Fpo pathways for F₄₂₀H₂ oxidation, *M. acetivorans* can only utilize Fpo, because it does not express its *frh* and *vht* operons (19, 20).

M. barkeri also contains a second F₄₂₀-reducing hydrogenase-encoding operon, *freAEGB*, which lacks the gene *D* present in the *frhADGB* operon (47). Subunit E does not show homology to subunit D that encodes a putative hydrogenase maturation protease or any other protein in the database. Nonetheless, the *fre* operon encodes a hydrogenase that is 85-87% identical to Frh. Also, all the important structural and catalytic residues of Frh are conserved in Fre. Thus, it has been proposed that Fre might be functional if it undergoes processing by FrhD (19). However, deletion of *fre* from *M. barkeri* does not have any effect on its growth. Moreover, Fre is also not able to substitute for the role of Frh in the Δfrh mutant (24). Therefore, Fre is not functional under the conditions tested.

The third type of hydrogenase, Vht, catalyzes the reversible reduction of the membrane-soluble electron carrier MP with H₂ (Figure 4.1) (4, 13, 19). MPH₂ acts as an electron donor for reduction of the CoM-S-S-CoB heterodisulfide using HdrED (12). Subsequently, CoM-SH and CoB-SH are used to reduce methyl group in the terminal methanogenic step. Not only have each of the individual reactions in this H₂:heterodisulfide oxidoreductase system been demonstrated using purified *M. mazei* enzymes and chemically synthesized MP (4, 11, 13, 22), the entire electron transport chain has also been reconstituted *in vitro* with *M. mazei* membrane preparations (22). Biochemical and genetic investigations in *M. mazei* and *M. barkeri* (24, 25, 36), have implicated necessity of this oxidoreductase system in each of the four methanogenic pathways (12). The source of H₂ in the CO₂ reduction and methyl-respiration pathways is external (12, 20, 38), whereas in the acetoclastic (35, 36) and methylotrophic (24, 25) pathways, H₂ is presumably produced from Fd_{red} and F₄₂₀H₂ by Ech and Frh hydrogenases, respectively (Figure 4.1). This proposal is consistent with the phenotype of an *M. barkeri* tetracycline (Tc)-regulated conditional *vht* mutant (P_{tet}*vht*) that is unable to grow on any of the methanogenic substrates tested under non-permissive conditions. However, Vht is not required for growth on methanol in the Δ *frh* mutant background. This is probably because, in the double Δ *vht frh* mutant, the Frh/Vht H₂-cycling is disrupted, thereby allowing use of Fpo for electron transfer from F₄₂₀H₂ to the heterodisulfide. In contrast, when Vht is deleted in the presence of Frh in the cell, the faster Frh enzyme out competes Fpo and disposes off electrons from F₄₂₀H₂ on to H₂ gas, which escapes from the

cell (25). Thus, despite its importance, Vht is not essential for growth of *M. barkeri* when Frh is absent from the cell.

While all three *Methanosarcina* species possess two operons, *vhtGACD* and *vhxGAC*, encoding the two MP-dependent hydrogenases, Vht and Vhx, *M. mazei* contains a third *vhoGAC* operon as well (14, 18, 31). The Vho and Vht enzymes are ca. 95% identical, however, Vhx displays only ca. 50% amino acid sequence identity to the other two hydrogenases. The deduced sequences of the Vht/Vhx/Vho enzymes from the three species possess all the important structural and catalytic residues. Thus, it has been proposed that in spite of missing the maturation protease-encoding gene D, *vhx* and *vho* operons might encode functional hydrogenases if the VhtD protein can process them by acting in *trans* (19). However, a deletion mutant of *vhx* in *M. barkeri* does not exhibit any growth defect. Moreover, in the $P_{tet}vht$ mutant, Vhx is not able to substitute for the role of Vht (25). Thus, Vhx is not functional under the conditions tested.

All [NiFe] hydrogenases require posttranslational modification to become enzymatically active (5). Although this modification has not been examined in *Methanosarcina*, it has been extensively studied in *Escherichia coli*, where the gene products of *hypABCDE* and *hypF* are responsible for maturation of hydrogenases by assembly of their bimetallic catalytic center. Homologs of these genes are found in each of the sequenced *Methanosarcina* genomes (14, 18, 31), suggesting that posttranslational activation might occur by similar mechanisms in these organisms.

It is evident from the aforementioned data that hydrogenases play an important role in *M. barkeri* physiology in each of the four methanogenic pathways. However, these data also highlight the dichotomy of the electron transport chains of *M. barkeri*, which comprise of both H₂-dependent and -independent branches. Because little is known about the latter pathways, we constructed and characterized hydrogenase deletion mutants in various combinations, including a hydrogenase minus quintuple mutant of *M. barkeri* that is able to grow methylotrophically.

4.3 MATERIALS AND METHODS

4.3.1 Media and growth conditions

Methanosarcina strains were grown as single cells (45) at 37° C in high salt (HS) broth medium (34) or on agar-solidified medium as described (6). Growth substrates provided were methanol (125 mM in broth medium and 50 mM in agar-solidified medium) or sodium acetate (120 mM) under a headspace of either N₂/CO₂ (80/20%) mix at 50 kPa over ambient pressure or H₂/CO₂ (80/20%) mix at 300 kPa over ambient pressure. Cultures were supplemented as indicated with 0.1% yeast extract (YE), 0.1% casamino acids (CAA), 10 mM sodium acetate, 10 mM pyruvate or 100 mM pyruvate. Puromycin (CalBioChem, San Diego, CA) was added at 2 µg/ml for selection of the puromycin transacetylase (*pac*) gene (42). 8-Aza-2,6-diaminopurine (8-ADP) (Sigma, St Louis, MO) was added at 20 µg/ml for selection against the presence of *hpt* (42). Tetracycline (Tc) was added at 100 µg/ml to induce the tetracycline-regulated

PmcrB(tetO) promoter (21). Standard conditions were used for growth of *Escherichia coli* strains (49) DH5 α / λ -*pir* (39) and DH10B (Stratagene, La Jolla, CA), which were used as hosts for plasmid constructions.

4.3.2 DNA methods and plasmid constructions

Standard methods were used for plasmid DNA isolation and manipulation in *E. coli* (3). Liposome mediated transformation was used for *Methanosarcina* as described (33). Genomic DNA isolation and DNA hybridization were as described (6, 34, 52). DNA sequences were determined from double-stranded templates by the W.M. Keck Center for comparative and functional genomics, University of Illinois. Plasmid constructions are described in tables 4.1 and 4.2.

4.3.3 Construction of hydrogenase deletion mutants

The construction and genotype of all *Methanosarcina* strains is presented in table 4.3. Carl G. Radosevich constructed the $\Delta echABCDEF$ (Figure 4.2) single mutant in the Δhpt (WWM85) (21) background of *M. barkeri* Fusaro by the markerless genetic exchange method using pCGR10 (42). The mutant was isolated using methanol as the growth substrate and was confirmed by PCR. The $\Delta frh fre$ double mutant was isolated by deletion of *freAEGB* in the $\Delta frhADGB$ mutant (25) using pGK6 (24) by the markerless method of genetic exchange (42). The mutant was isolated using methanol plus H₂/CO₂ as the growth substrate. The *M. barkeri* locus containing *vhtGACD*, *Mbar_A1843*, *Mbar_A1842*

and *vhxGAC*; or *hypCDABE*, *vhtGACD*, *Mbar_A1843*, *Mbar_A1842* and *vhxGAC*, was deleted from the Δfrh *fre* double mutant using XhoI/NotI-digested 5.6 kb pGK11 or ApaI/NotI-digested 6 kb pGK12, respectively, by the homologous gene replacement method (52) in the presence of methanol (Figure 4.3). This gave rise to the two mutants, Δfrh *fre vht vhx Mbar_A1842 Mbar_A1843* and Δhyp *frh fre vht vhx Mbar_A1842 Mbar_A1843*. The

Figure 4.3 Genomic organization of operons encoding methanophenazine-dependent hydrogenases (Vht/Vhx) and hydrogenase maturation proteins (Hyp) in *Methanosarcina barkeri* (adapted from (25)). There are two operons, *vhtGACD* and *vhxGAC*, encoding the two hydrogenases, Vht and Vhx, respectively, that are ca. 50% identical. The *vhx* operon lacks gene D that encodes a putative hydrogenase maturation protein presumed to be essential for post-translational modification of the *cis*-encoded hydrogenase. The intergenic region between *vht* and *vhx* contains two genes, *Mbar_A1842* and *Mbar_A1843*. While *Mbar_A1842* encodes a peptidoglycan-binding domain containing protein, *Mbar_A1843* encoded protein shows ca. 38% amino acid identity to the activator of Hsp90 ATPase 1 family protein of some organisms. *M. barkeri* also contains a *hypCDABE* operon that encodes proteins presumed to be required for synthesis and insertion of the [NiFe] bimetallic catalytic center in its hydrogenases. Other open reading frames (ORFs) are shown as gray arrows.

echABCDEF operon was deleted in Δfrh , Δvht *frh* (25) and Δfrh *fre vht vhx*

Mbar_A1842 Mbar_A1843 mutant backgrounds to obtain Δech *frh*, Δech *vht frh*

and Δech *frh fre vht vhx Mbar_A1842 Mbar_A1843* mutants, respectively, using

the homologous recombination-mediated gene replacement method (52). In this

method, ApaI/NotI cut 5.6 kb region of pGK9 was transformed into the mutant

backgrounds and the transformants were selected using methanol with

supplementation (YE, CAA, acetate and/or pyruvate) and puromycin. All the mutants were confirmed by DNA hybridization (Figures 4.4, 4.5, 4.6 and 4.7). *vht* operon was rendered Tc-dependent in the Δech background by replacing its native promoter with the Tc-regulated *PmcrB(tetO3)* promoter (21). For this, *NcoI*/*SpeI*-digested 7.0 kb fragment of pGK61A (25) was transformed into Δech and the transformants were selected in presence of methanol, Tc and puromycin. The Δech *P_{tet}vht* strain was confirmed by PCR.

4.3.4 Determination of growth characteristics

For growth rate determinations, cultures were grown on methanol or methanol plus H_2/CO_2 (Δfrh and $\Delta frh fre$) to mid-log phase (optical density at 600 nm $[OD_{600}]$ ca. 0.5). Approximately 3% inoculum of the culture (or 10%, in case of acetate) was then transferred to fresh medium in four replicates and incubated at 37° C. Growth was quantified by measuring OD_{600} . Generation times were calculated during exponential growth phase and lag phase was defined as the time required to achieve half-maximal OD_{600} .

Due to the ability of *Methanosarcina* strains to grow on endogenous substrates found in agar (43), growth of Tc-regulated strains was tested on nylon membranes using the spot-plate method. In this, each of the strains was first

adapted for at least 15 generations to the substrate of interest. Once grown to saturation, 10 ml cultures of all strains were washed three times with plain-HS medium and then resuspended in 5 ml final volume. Subsequently, they were serially diluted 10-fold from 10^{-1} to 10^{-7} . The spotting plate was then prepared by placing three layers of GB004 paper (Whatman, NJ), two layers of GB002 paper (Schleicher & Schuell BioScience, NH) and 1 layer of 3MM paper (Whatman, NJ). Subsequently, this stack of papers was soaked in 43 ml of HS-medium containing the substrate of interest with and without Tc. A 0.22 μ M nylon membrane (GE Water and Process Technologies, PA) was then placed on top of the paper stack. Finally, 10 μ l of the undiluted culture and each of the serial dilutions was spotted on the plate using a multi-channel pipettor. The plate was then sealed with parafilm and incubated for at least two weeks to check growth.

4.3.5 Cell suspension experiments

Cells grown on methanol or methanol plus H_2/CO_2 (Δfrh and $\Delta frh fre$) were collected in late exponential phase (OD_{600} = 0.6-0.7) by centrifugation at 5,000 x g for 15 minutes at 4°C. They were then washed once with anaerobic HS PIPES buffer, 50 mM PIPES (pH 6.8), 400 mM NaCl, 13 mM KCl, 54 mM $MgCl_2$, 2 mM $CaCl_2$, 2.8 mM cysteine, 0.4 mM Na_2S and resuspended in the same buffer to a final concentration of 10^9 cells/ml. Cells were counted visually using the Petroff-Hausser counting chamber (Hausser Scientific, PA). All assay mixtures contained 2 ml of the suspension and were conducted under strictly anaerobic conditions in 25 ml Balch tubes sealed with butyl rubber stoppers. Puromycin (20

μg/ml) was added to prevent protein synthesis and as indicated the assay mixture contained 250 mM methanol under a headspace of N₂, H₂ or H₂/CO₂ (80/20%) at 250 kPa over the ambient pressure. Cells were held on ice until use and assays were started by transferring tubes to 37°C. For rate determination, gas phase samples were withdrawn at various time points and assayed for methane (CH₄) by gas chromatography at 225°C in a Hewlett Packard gas chromatograph (5890 Series II) equipped with a flame ionization detector. The column used was of stainless steel filled with 80/120 CarbopackTM B/3% SPTM-1500 (Supelco, Bellefonte, PA) with helium as the carrier gas. For total CH₄ and CO₂ production, assays were incubated at 37°C for 36 hours and then gas phase samples were withdrawn. These samples were analyzed by GC at 225°C in a Hewlett Packard gas chromatograph (5890 Series II) equipped with a thermal conductivity detector. A stainless steel 60/80 Carboxen-1000 column (Supelco, Bellefonte, PA) with helium as the carrier gas was used. Total cell protein was determined using the Bradford method (8) after 1 ml of the cells was lysed by resuspending it in ddH₂O with 1 μg/ml RNase and DNase.

4.4 RESULTS

4.4.1 Isolation of a series of *M. barkeri* hydrogenase deletion mutants

The hydrogenases of *M. barkeri* Fusaro were deleted sequentially in a specific order, which is depicted in figure 4.8. This is because, certain hydrogenase deletion mutants are only viable, in other hydrogenase mutant backgrounds (25). In addition, to simplify isolation of the hydrogenase mutant

that lacks both the operons encoding MP-dependent hydrogenases, *vhxGAC* and *vhtGACD*, we also deleted the genes present between these operons in the mutant, *Mbar_A1842* and *Mbar_A1843* (Figure 4.3). The growth characteristics of all hydrogenase mutants were then determined on various methanogenic substrates.

Figure 4.8 Flowchart depicting isolation of a series of *M. barkeri* hydrogenase deletion mutants. The first row represents single hydrogenase deletion mutants (blue boxes). These were used as backgrounds for deletion of other hydrogenase encoding operons; *echABCDE*, *freAEGB*, *vhxGAC*, *vhtGACD* or *hypCDABE*, using different growth substrates, as indicated. The mutants in red were isolated in this study, whereas, other mutants were constructed in previous studies. * mutants were also deleted of genes present in between *vhx* and *vht* operons, *Mbar_A1842* and *Mbar_A1843*. The tetracycline (Tc)-regulated conditional *vht* mutant is denoted as *P_{tet}vht*.

4.4.2 All three types of hydrogenases are needed for growth of *M. barkeri* via the CO₂ reduction pathway

In this pathway, CO₂ is reduced to CH₄ in a step-wise manner using H₂ gas as the electron donor (46). Thus, at every reduction step, a hydrogenase is

needed to harvest electrons from H₂ and funnel them into the pathway. Ech hydrogenase is required to provide Fd_{red} for reduction of CO₂ to the formyl level (36), whereas, F₄₂₀H₂ produced by Frh hydrogenase is needed to reduce methenyl and methylene groups (24). Vht hydrogenase generates MPH₂ for methyl group reduction (25). Consistent with the role of each of these hydrogenases, none of the hydrogenase deletion mutants that lack Ech, Frh and/or Vht (all except Δfre and Δvhx mutants) are able to grow using this substrate (Table 4.4). Also, they are unable to produce CH₄ from H₂/CO₂ in resting cell suspensions (Table 4.5). However, the Δfrh mutant converts a very small amount of the substrate to CH₄ in cell suspensions, suggesting an alternate source of F₄₂₀H₂ in *M. barkeri* that is unable to support its growth. It is important to note that as observed in previous studies (24, 25), our data also show that Fre and Vhx hydrogenases are not able to substitute for the role of Frh and Vht hydrogenases in the single Δfrh and $P_{tet}vht$ mutants, respectively. Thus, they are not functional under the conditions tested.

4.4.3 *M. barkeri* hydrogenases are dispensable during its methylotrophic growth

With the exception of $P_{tet}vht$ and $\Delta ech P_{tet}vht$, all other hydrogenase mutants are able to grow on methanol (Table 4.6). Furthermore, they are capable of converting methanol to CH₄ and CO₂ in a 3:1 ratio in resting cell suspensions (Table 4.5). This suggests that in all these mutants, including the quintuple hydrogenase mutant, all 6 electrons derived from the oxidation of 1 methanol

methyl group to CO₂ are channeled to the terminal step for reduction of 3 methanol methyl groups to CH₄, via H₂-independent pathways. These pathways

allow the hydrogenase mutants to achieve growth yields that are comparable to the isogenic parental strain (Table 4.6). However, the mutants exhibit variable rates of growth and CH₄ production in resting cell suspensions (Table 4.7).

Consistent with previous observations (24), our results here show that the Δfrh

^c*M. barkeri* Fusaro parent strain in which all deletions were constructed.

mutant grows twice as slow as the isogenic parental strain. The Δfrh fre double mutant exhibits similar growth characteristics as the single Δfrh mutant. Other hydrogenase mutants, except Δfre and Δvhx , grow slightly slower than the parental strain. All hydrogenase mutants lacking Frh exhibit lower rates of CH₄ production than the isogenic parental strain in resting cell suspensions (Table 4.7). This suggests that the H₂-independent F₄₂₀H₂:heterodisulfide pathway is less efficient than the Frh-involving pathway. In contrast, the Δech mutant has a comparable rate of CH₄ production to the parental strain, implying that the H₂-independent Fd_{red}:heterodisulfide pathway is as efficient as the pathway involving Ech.

To test growth of Tc-regulated conditional *vht* mutants with and without Tc (Figure 4.9), 10-fold dilutions of cultures of these mutants and the wild-type strain (WWM85, Table 4.3) were spotted on a nylon membrane in the presence of

Figure 4.9 Growth of tetracycline-regulated *vht* ($P_{tet}vht$) mutants of *M. barkeri* on plates containing methanol. 10-fold serial dilutions of WWM85 (wt *vht*, Table 4.3), $P_{tet}vht$ and Δech $P_{tet}vht$ strains were spotted on methanol plates with and without tetracycline (Tc), as described in Materials and Methods. The dilution factors are indicated at the bottom of each plate. Unlike wt *vht*, which was able to grow in the presence and absence of Tc, $P_{tet}vht$ and Δech $P_{tet}vht$ strains could only grow in the presence of Tc at higher dilutions. Growth of these strains at 0 dilution factor (undiluted) without Tc could be due to presence of residual Vht protein within the cell. Suppressors were detected for both $P_{tet}vht$ strains in the absence of Tc at higher dilutions.

methanol as the growth substrate. Unlike the wild-type strain that grew up with and without Tc, the $P_{tet}vht$ and $\Delta ech P_{tet}vht$ strains were only able to grow in the presence of Tc, when *vht* is expressed. However, in the absence of Tc, the $P_{tet}vht$ strains grew up at the lowest dilution. This growth could be attributed to residual Vht protein in the cells at this dilution. Also, a few $P_{tet}vht$ mutant colonies were seen at higher dilutions. These could be suppressors with mutation in the Tc-regulated *PmcrB(tetO3)* promoter and/or the *tetR* gene, as previously seen for Tc-regulated mutant of *hdrED* operon that encodes the essential HdrED enzyme (9). Thus, our data suggest that Vht is essential for methylotrophic growth of *M. barkeri* in the wild-type and Δech mutant background. Also, Vhx present in $P_{tet}vht$ strains is not able to substitute for the role of Vht, indicating its non-functionality.

4.4.4 Hydrogenase activity is essential for methanol utilization via the methyl respiration pathway

In this pathway, methyl group of methanol is reduced to CH_4 using electrons derived from the oxidation of H_2 by the MP-dependent hydrogenase Vht (20, 38). Thus, unlike in the methylotrophic pathway, 25% methanol methyl groups do not need to be oxidized to CO_2 to obtain reducing equivalents for reduction of the rest of methyl groups to CH_4 .

All the hydrogenase deletion mutants containing the Vht hydrogenase are able to convert methanol plus H_2 to CH_4 in resting cell suspensions without detectable CO_2 production or, in other words, via the methyl respiration pathway (Δech , Δfrh , Δfre , Δvhx , $\Delta ech frh$ and $\Delta frh fre$, Table 4.5). Also, all these mutants,

except the Δech mutant, can grow using methanol plus H₂/CO₂ as the substrate (Table 4.8). As reported in a previous study (36), we were able to restore growth

Table 4.8 Growth^a of *M. barkeri* Fusaro strains^b on methanol plus H₂/CO₂

of the Δech mutant by supplementation of HS-methanol plus H_2/CO_2 medium with 100 mM pyruvate. On the basis of this observation, it was postulated that Ech produces Fd_{red} required for pyruvate biosynthesis in the methyl respiration pathway. Therefore, it is surprising that the $\Delta ech frh$ double mutant does not display this biosynthetic defect. The double mutant grows using methanol plus H_2/CO_2 , albeit, twice as slow as the isogenic parental strain. Also, it exhibits a *ca.* 7-fold longer lag phase and a lower rate of CH_4 production in resting cell suspensions than the parental strain on this substrate (Table 4.7). Thus, these data suggest that there is an alternate pathway to obtain Fd_{red} for pyruvate biosynthesis, in the $\Delta ech frh$ double mutant. However, this pathway is not operational in the single Δech mutant.

To test the role of Vht in the methyl respiration pathway, growth of the conditional *vht* mutant ($P_{tet}vht$) was scored with and without Tc using the spot-plate method described in Materials and Methods (Figure 4.10). The $P_{tet}vht$

Figure 4.10 Growth of tetracycline-regulated *vht* mutant ($P_{tet}vht$) of *M. barkeri* on plates containing methanol under an atmosphere of H_2/CO_2 . 10-fold serial dilutions of WWM85 (wt *vht*, Table 4.3) and $P_{tet}vht$ strains were spotted on methanol plus H_2/CO_2 plates with and without tetracycline (Tc), as described in Materials and Methods. The dilution factors are indicated at the bottom of each plate. Unlike wt *vht*, which was able to grow in the presence and absence of Tc, $P_{tet}vht$ strain could only grow in the presence of Tc at higher dilutions. Growth of these strains at 0 dilution factor (undiluted) without Tc could be due to presence of residual Vht protein within the cell.

mutant is unable to grow using methanol plus H₂/CO₂ in the absence of Tc, when *vht* is not expressed. Growth of the mutant at lowest dilution without Tc is probably due to residual Vht protein in the cells. Thus, these data suggest that Vht is essential for growth of wild-type *M. barkeri* via the methyl respiration pathway. However, two mutants lacking the Vht and Frh hydrogenases, $\Delta vht\ frh$ and $\Delta frh\ fre\ vht\ vhx\ Mbar_A1842\ Mbar_A1843$, are able to grow using this pathway. This is because, these mutants convert methanol plus H₂ to CH₄ in resting cell suspensions, with less than 25% CO₂ production. This suggests that another hydrogenase can harvest electrons from H₂ for methyl group reduction, when both Vht and Frh hydrogenases are absent from the cell. This alternate pathway can only support *ca.* 50% growth yield and a nearly four-fold lower growth rate than the isogenic parental strain in the $\Delta vht\ frh$ and $\Delta frh\ fre\ vht\ vhx\ Mbar_A1842\ Mbar_A1843$ mutants (Table 4.8). Also, both these mutants exhibit a *ca.* three-fold longer lag phase than the parental strain. The rate of CH₄ production in resting cell suspensions in these mutants is also lower than the parental strain (Table 4.7). Hence, this alternate pathway seems to be less efficient than the pathway involving Vht.

Mutants that lack all three types of hydrogenases (Ech, Frh and Vht), $\Delta ech\ vht\ frh$ and $\Delta ech\ frh\ fre\ vht\ vhx\ Mbar_A1842\ Mbar_A1843$, convert methanol plus H₂ to CH₄ and CO₂ in a 3:1 ratio in resting cell suspensions. This suggests that they use methanol via the methylotrophic pathway, which is surprising, because the methyl oxidative pathway is known to be repressed in the presence of H₂ (36). The $\Delta hyp\ frh\ fre\ vht\ vhx\ Mbar_A1842\ Mbar_A1843$ mutant, which lacks the

Hyp proteins, also utilizes methanol plus H₂ methylotrophically in resting cell suspensions. Therefore, the Δhyp mutant is functionally equivalent to mutants that lack functional hydrogenases. The growth characteristics exhibited by these mutants on methanol plus H₂/CO₂ are similar to those on methanol alone. They also show similar rates of CH₄ production in resting cell suspensions on both substrates.

4.4.5 Aceticlastic growth requires Fd_{ox}- and MP-dependent hydrogenases

Acetate utilization involves reduction of methyl group of acetate to CH₄ using Fd_{red}, which is derived from oxidation of its carbonyl group (15). It has been proposed that Ech and Vht hydrogenases mediate electron transfer from Fd_{red} to the heterodisulfide, using H₂ as an intermediate (35, 36). Consistent with this proposal, none of the hydrogenase deletion mutants that lack either the Ech or the Vht hydrogenase are able to grow on this substrate (Table 4.9).

4.5 DISCUSSION

In spite of their close evolutionary relatedness (31), the two *Methanosarcina* species, *M. barkeri* and *M. acetivorans*, exhibit basic differences in their energy-conserving electron transport chains. On one hand is the hydrogenotrophic *M. barkeri* species that uses H₂-dependent pathways for electron transfer on every methanogenic substrate examined, including H₂/CO₂ (12), methanol plus H₂/CO₂ (20), methanol (24, 25) and acetate (Figure 4.1) (35, 36). On the other hand, the non-hydrogenotrophic *M. acetivorans* species

employs H₂-independent methylotrophic and aceticlastic electron transport chains (19, 20). To further understand the differences between the electron

transfer circuits of these two species, we deleted all hydrogenases from *M. barkeri* to convert it into an *M. acetivorans*-like species. This is significant, because hydrogenases have been shown to be intricately involved in each of the methanogenic pathways of *M. barkeri*. Nevertheless, this study proves that they are not essential for growth of *M. barkeri*, thereby implicating presence of unidentified, and perhaps novel, H₂-independent electron transfer pathways. Moreover, we have also been able to construct a useful hydrogenase-minus *M. barkeri* background that can be utilized for complementation studies with *M. acetivorans* electron-transport chain components. While not required for methylotrophic growth, our study shows that hydrogenases are absolutely essential for growth via the CO₂ reduction, methyl-respiration and aceticlastic pathways. The data presented here also suggest that hydrogenases are needed to exert inhibitory effects of H₂ on the methyl oxidative pathway. Furthermore, our results confirm the putative role of Hyp proteins in the maturation of at least one of the [NiFe] hydrogenases of *M. barkeri*, Ech.

In the CO₂ reduction pathway, reduction of CO₂ to CH₄ presumably requires three kinds of electron donors, Fd_{red}, F₄₂₀H₂ and MPH₂ (46). Consistent with this proposal, each of the three kinds of hydrogenases that reduce Fd_{ox} (Ech), F₄₂₀ (Frh) or MP (Vht) is needed for growth on H₂/CO₂. Notably, unlike Frh and Vht, Fre and Vhx are not able to provide sufficient amount of F₄₂₀H₂ and MPH₂, respectively, for hydrogenotrophic growth. This could be due to low expression of *fre* and *vhx* operons, absence of post-translational processing, mutations in structural or catalytic residues or some combination of these (19).

The methylotrophic methanogenic pathway involves two different electron transport chains, one that transfers electrons from Fd_{red} to the heterodisulfide, whereas the other reduces the heterodisulfide using F_{420}H_2 as an electron donor (23, 36). In *M. barkeri*, these chains presumably merge, because Ech and Frh hydrogenases oxidize Fd_{red} and F_{420}H_2 , respectively, to produce a common intermediate, H_2 , which enters the energy-conserving H_2 :heterodisulfide oxidoreductase system using the Vht hydrogenase (Figure 4.1) (24, 25, 35, 36). This H_2 -cycling mechanism is the preferential mode of electron transfer in *M. barkeri*, at least from F_{420}H_2 . Nevertheless, like *M. acetivorans*, our study shows that *M. barkeri* is capable of methylotrophic growth in the absence of its hydrogenases, implicating presence of H_2 -independent electron-transport pathways from Fd_{red} and F_{420}H_2 to the heterodisulfide. The well-studied F_{420}H_2 :heterodisulfide oxidoreductase system (12) involving Fpo has been shown to solely account for electron transfer from F_{420}H_2 , in the absence of Frh in *M. barkeri* (Figure 4.1) (24). However, Fpo is nearly four-times slower than Frh. Consistent with this fact, all Frh-lacking hydrogenase deletion mutants exhibit lower rates of CH_4 production in resting cell suspensions than the strains containing Frh (Table 4.7). Nevertheless, Δfrh deletion mutants attain growth yields that are comparable to those of frh^+ strains (Table 4.6). This is because, the magnitude of the proton-motive force generated by both Frh- and Fpo-containing pathways is equal ($4\text{H}^+/2\text{e}^-$) (24). *M. acetivorans* probably uses the F_{420}H_2 :heterodisulfide oxidoreductase system, because it harbors an *fpo* operon (18) that is expressed (26, 27), but an *frh* operon that is not expressed (19).

Moreover, the *fpo* operon most likely encodes a functional enzyme, because all structural and catalytic amino acid residues that are present in *M. barkeri* Fpo, are conserved in *M. acetivorans* Fpo (24). Interestingly, unlike *M. barkeri* Fpo, *M. acetivorans* Fpo allows high rates of methylotrophic CH₄ production in resting cell suspensions (161 nmol min⁻¹ mg⁻¹) (7). This could be attributed to a difference in expression levels, enzymatic properties or both, of the enzyme from the two species.

The H₂-independent Fd_{red}:heterodisulfide oxidoreductase system is a subject of investigation in both species. In *M. acetivorans*, a putative Fd_{red}:MP oxidoreductase, Rnf, has been identified that is essential for growth on acetate (28). However, its deletion does not prevent methylotrophic growth by disproportionation of methanol in a 3:1 CH₄:CO₂ ratio, thus indicating the presence of a second Fd_{red} oxidoreductase. In a recent study, such an enzyme was proposed to be the soluble HdrA1B1C1 heterodisulfide reductase, which mediates direct electron transfer from Fd_{red} to the CoM-S-S-CoB heterodisulfide (9). Although Rnf is absent in *M. barkeri*, the operon encoding HdrA1B1C1 is present in its genome (Figure 4.11) (31). Therefore, HdrA1B1C1 could be responsible for transferring electrons from Fd_{red} to the heterodisulfide in *M. barkeri* (Figure 4.1). However, this cytoplasmically catalyzed exergonic reaction is not involved in direct energy conservation (9). This is in disagreement with our data, which show that the *M. barkeri* H₂-independent route is as efficient as the H₂-cycling pathway in conserving energy. This is because, the Δech hydrogenase mutant exhibits comparable rates of CH₄ production and growth

yields to the isogenic *ech*⁺ parental strain (Tables 4.6 and 4.7). This suggests that *M. barkeri* may possess another unique Fd_{red} oxidoreductase. Alternatively, as postulated by Buan *et al* (9), HdrA1B1C1 might be involved in energy

Figure 4.11 Genomic organization of operons encoding soluble heterodisulfide reductase (HdrA1B1C1) in *Methanosarcina* species. All three species contain the HdrA1B1C1-encoding operon (*hdrA1C1B1*).

energy conservation using an electron bifurcation mechanism, wherein, for every CoM-S-S-CoB reduced, a molecule of coenzyme F₄₂₀ also undergoes reduction. Subsequently, electron channeling from F₄₂₀H₂ via the F₄₂₀H₂:heterodisulfide oxidoreductase system (12) would conserve energy. However, the bifurcation pathway would conserve half the amount of energy than the H₂-cycling pathway, because only 50% of Fd_{red} electrons flow through the F₄₂₀H₂:heterodisulfide

oxidoreductase system for energy conservation. Thus, the identity of the Fd_{red} oxidoreductase in *M. barkeri* remains unknown.

In the methyl respiration pathway, energy is conserved via the H₂:heterodisulfide oxidoreductase system, wherein, Vht oxidizes H₂ to release electrons for reduction of the CoM-S-S-CoB heterodisulfide. However, *M. barkeri* Δvht *frh* and Δfrh *fre vht vhx* mutants probably employ H₂-independent Fd_{red}:heterodisulfide electron transport chain for energy conservation. This is because, Ech is the only functional hydrogenase present in both these mutants. Therefore, it must be responsible for oxidizing H₂ to provide Fd_{red} for CoM-S-S-CoB reduction. However, it is unclear why the conditional *vht* mutant (*P_{tet}vht*) fails to utilize this Ech-dependent pathway for growth via the methyl respiration pathway. It is apparent that presence of *Frh*, prevents Fd_{red}-dependent respiration in the *P_{tet}vht* mutant, however, this needs to be tested.

Our results suggest that hydrogenases mediate repression of the methyl oxidative pathway by H₂. The fact that Ech is required for biosynthesis on methanol plus H₂/CO₂, but not on methanol alone, suggests that the methyl oxidative pathway is repressed in presence of H₂, precluding the use of CHO-methanofuran dehydrogenase (Fmd)-catalyzed reaction for Fd_{red} synthesis (36). However, H₂ alone is insufficient for this repression, because Δech *frh vht* mutants are able to grow methylotrophically in presence of methanol plus H₂/CO₂. In addition, unlike the single Δech mutant, the Δech *frh* double mutant can grow via the methyl-respiration pathway without pyruvate supplementation, thus implying that it probably fulfills its biosynthetic needs of Fd_{red} by oxidizing the

methanol methyl group to CO₂. Hence, H₂ needs to be converted to F₄₂₀H₂ and/or Fd_{red} by Ech and Frh hydrogenases, respectively, to exert an inhibitory effect on the methyl oxidative pathway. The inhibition might occur in two possible ways. Firstly, in the presence of H₂ and the respective hydrogenases, F₄₂₀ and Fd_{ox} pools might get completely reduced, leading to thermodynamic repression of the methyl oxidative pathway. Alternatively, F₄₂₀H₂ and/or Fd_{red} might be involved in direct inhibition of one or more enzymes of the methyl oxidative branch.

Our study also provides experimental evidence for the hypothesis that Hyp proteins are involved in post-translational modification of [NiFe] hydrogenases in *M. barkeri* (5, 19). Unlike *ech*⁺ Δ *frh frh vht vhx* strain, the *ech*⁺ Δ *hyp frh frh vht vhx* mutant is unable to grow via the methyl reduction pathway using Ech, suggesting that this hydrogenase is non-functional in the Δ *hyp* mutant. Thus, Hyp proteins are essential for maturation of the [NiFe] Ech hydrogenase.

Deletion of *Mbar_A1842* and *Mbar_A1843* genes might have contributed to the phenotype of Δ *frh frh vht vhx Mbar_A1842 Mbar_A1843, Δ *hyp frh frh vht vhx Mbar_A1842 Mbar_A1843, and Δ *ech frh frh vht vhx Mbar_A1842 Mbar_A1843* hydrogenase mutants. *Mbar_A1842* encodes for a peptidoglycan-binding domain containing protein with an unknown function (2, 32, 40). Homologs of this gene are present in the other two *Methanosarcina* species, *M. mazei* (MM2174, 71% amino acid identity (10)) and *M. acetivorans* (MA1145, 55% amino acid identity (10)) at the same genomic location, that is, between the *vhx* and *vht* operons (2, 32). The *Mbar_A1843* homolog present in *M. mazei* (MM2173, 57% amino acid identity (10)) is also located at the same site,**

however, the *M. acetivorans* homolog (MA3620, 36% amino acid identity (10)) is present elsewhere in the chromosome (2, 32). Although the function of the protein encoded by this gene is not known, it shows *ca.* 38% amino acid sequence identity (10) to the activator of Hsp90 ATPase 1 family protein from *Nostoc punctiforme* and *Sphingobacterium spiritivorum* (2). Thus, the physiological roles of proteins encoded by *Mbar_A1842* and *Mbar_A1843* are currently unknown. In the future, we plan to complement the aforementioned hydrogenase mutants with these two genes, to test their contribution to the phenotype of the mutants.

Lastly, it is possible that *M. barkeri* and *M. acetivorans* have different physiologies due to a difference in their habitats. Methanogens exist in environments, where they have to compete with other micro-organisms for H₂. These include denitrifiers, sulfate-reducing bacteria, iron-reducing bacteria and manganese-reducers, which have a higher affinity for H₂ than methanogens. In its high-salt marine habitat, *M. acetivorans* exists as disaggregated single cells (45) and is therefore more prone to lose H₂ gas to competing micro-organisms in its environment, especially sulfate reducers, because such habitats are rich in sulfate. This might be the reason why *M. acetivorans* foregoes H₂-dependent electron transport pathways. In contrast, freshwater organisms like *M. barkeri* that exist as large multicellular aggregates (31), have a higher chance of retaining H₂ gas within the aggregates, enabling them to use it as an electron carrier. Nonetheless, these organisms might resort to H₂-independent pathways, when conditions like Ni-limitation prevent synthesis of hydrogenases (1). In

future, we plan to identify components of these electron transport pathways by microarray expression analysis of the quintuple hydrogenase *M. barkeri* mutant.

CHAPTER 5

SUMMARY AND FUTURE DIRECTIONS

5.1 INTRODUCTION

In every methanogenic pathway, methane (CH_4) production is accompanied by formation of a heterodisulfide (CoM-S-S-CoB) of coenzyme M (CoM-SH) and coenzyme B (CoB-SH). The CoM-S-S-CoB heterodisulfide needs to be reduced to regenerate the free coenzymes necessary for sustaining methanogenesis. In *Methanosarcina*, this is accomplished via three energy-conserving electron transport chains that differ in the nature of electron donors, which are H_2 , reduced F_{420} (F_{420}H_2) or reduced ferredoxin (Fd_{red}) (reviewed in (5, 6)). Although the Fd_{red} :heterodisulfide pathway is not well-understood, the other two electron transport systems have been reconstituted *in vitro* in *Methanosarcina mazei* (1, 11). In the H_2 :heterodisulfide system, electrons derived from oxidation of H_2 by the methanophenazine-dependent hydrogenase (Vht) are used to reduce the membrane-soluble electron carrier methanophenazine (MP). Subsequently, oxidation of reduced MP (MPH_2) releases electrons for reduction of CoM-S-S-CoB by the heterodisulfide reductase (HdrED). On the other hand, in the F_{420}H_2 :heterodisulfide system, the F_{420}H_2 dehydrogenase (Fpo) oxidizes F_{420}H_2 , concomitantly pumping two protons outside the cell and passing electrons to MP. MPH_2 oxidation is then coupled to CoM-S-S-CoB reduction, as in the H_2 :heterodisulfide system. In both oxidoreductase systems, four protons are translocated per two electrons

transferred to CoM-S-S-CoB. This proton-motive force can be used for ATP synthesis by an ATP synthase. One or more of these systems is employed by *Methanosarcina* species to conserve energy during growth on a particular methanogenic substrate. For instance, growth using H₂/CO₂ or methanol plus H₂/CO₂ involves utilization of H₂:heterodisulfide system (5). However, Fd_{red}:heterodisulfide and F₄₂₀H₂:heterodisulfide systems are needed to allow growth on methylated C-1 compounds like methanol, because the methyl oxidative pathway produces reducing equivalents in the form of Fd_{red} and F₄₂₀H₂. Hence, Fpo was considered indispensable for methylotrophic methanogenesis (1). Aceticlastic growth involves use of Fd_{red}:heterodisulfide pathway to harvest electrons from Fd_{red}, which is generated from oxidation of carbonyl group of acetate (15, 16). In this study, we employed genetic tools to enhance our understanding of these energy-conserving systems in *Methanosarcina*, using *Methanosarcina barkeri* as our model organism.

5.2 SIGNIFICANT FINDINGS

5.2.1 *M. barkeri* possesses a branched F₄₂₀H₂:heterodisulfide electron transport chain, with a Frh/Vht H₂-cycling branch and another branch involving Fpo

Based on *in vitro* biochemical studies, the Fpo-involving F₄₂₀H₂:heterodisulfide oxidoreductase system was presumed to be required during methylotrophic growth (1). However, in Chapter 2, we found out that deletion of Fpo-encoding operon in *M. barkeri* does not affect growth on methanol or other methanogenic substrates tested. In contrast, loss of the fully

reversible F_{420} -reducing hydrogenase (Frh) (17) from the cell severely affects methylotrophic growth, implicating its involvement in $F_{420}H_2$:heterodisulfide electron transport chain. Nonetheless, our data also showed that Fpo is responsible for slow growth of the Δfrh mutant on methanol, because absence of both Frh and Fpo from the cell abolishes growth on this substrate. Thus, *M. barkeri* employs both these enzymes to harvest electrons from $F_{420}H_2$, however, it clearly prefers Frh over Fpo. A plausible reason for this choice could be the ability of Frh to support a higher rate of CH_4 production than Fpo.

H_2 produced by Frh was proposed to feed into the H_2 :heterodisulfide oxidoreductase system for energy conservation. To verify this, in Chapter 3, we tried to delete the input module of this system, Vht, without any success, thereby implying that Vht is essential for growth of *M. barkeri*. We proved this assumption correct, by isolating a tetracycline (Tc)-regulated conditional *vht* mutant ($P_{tet}vht$) that is unable to grow on any methanogenic substrate tested under non-permissive conditions, including on methanol. Thus, this result supported the idea that Vht consumes H_2 during methylotrophic growth. This hypothesis was further bolstered by the fact that repression of *vht* expression resulted in a rapid increase in H_2 partial pressure, accompanied with growth inhibition. This suggested that H_2 uptake by Vht is essential for viability of *M. barkeri*. However, Vht is not required in mutants lacking the H_2 -producing Frh hydrogenase, which is consistent with functional coupling of Frh and Vht hydrogenases in a “ H_2 -cycling” mechanism (18). In this mechanism, cytoplasmic Frh hydrogenase couples $F_{420}H_2$ oxidation to reduction of two protons within the cytoplasm to form

H₂ gas. Subsequently, the gas diffuses out of the cell to periplasmic Vht hydrogenase, where it is oxidized to regenerate two protons, thus creating an energy-conserving trans-membrane proton gradient. H₂-cycling has been proposed in various anaerobic micro-organisms (4, 13, 18, 19), however, this is the first study to provide direct experimental evidence for its occurrence.

5.2.2 *M. barkeri* possesses a branched Fd_{red}:heterodisulfide electron transport chain, with an Ech/Vht H₂-cycling branch and another branch involving an unidentified Fd_{red} oxidoreductase

M. barkeri methylotrophic Fd_{red}:heterodisulfide electron transport chain has been proposed to comprise of the ferredoxin (Fd_{ox})-dependent hydrogenase Ech, which couples Fd_{red} oxidation to H₂ production, and the H₂:heterodisulfide oxidoreductase system (15, 16). Thus, this pathway resembles the Frh-dependent F₄₂₀H₂:heterodisulfide system. Also, analogous to Frh and Vht, Ech and Vht can undergo H₂-cycling, because the active site of Ech is cytoplasmic, whereas that of Vht is periplasmic. In Chapter 3, we provided supporting evidence for this hypothesis, because the Ech-containing $\Delta vht\ frh$ double mutant produced more H₂ from methanol than the single Δfrh mutant, in which Ech/Vht H₂-cycling is not disrupted. Nevertheless, Δech mutants isolated in Chapter 4 do not display a defect in methylotrophic growth, implying presence of a H₂-independent Fd_{red}:heterodisulfide pathway involving an as yet unidentified Fd_{red} oxidoreductase. Moreover, this pathway is as efficient as Ech/Vht H₂-cycling in supporting growth on methanol. Additionally, it allows growth via the methyl respiration pathway in $\Delta vht\ frh$ and $\Delta vht\ vhx\ frh\ fre$ strains, when Fd_{red} is made

available by the action of Ech. However, the Ech–catalyzed pathway does not allow methanogenesis to proceed at rates as high as the Vht-containing H₂:heterodisulfide system. The H₂-independent Fd_{red}:heterodisulfide pathway is not able to support growth on acetate. Thus, Ech and Vht are absolutely essential for acetoclastic growth.

5.2.3 Fre and Vhx hydrogenases are non-functional under tested conditions

In addition to *frhADGB* and *vhtGACD* operons, *M. barkeri* contains *freAEGB* and *vhxGAC* operons, which encode putative F₄₂₀-dependent (Fre) and MP-dependent hydrogenases (Vhx), respectively (14). Both these operons are missing gene D that encodes a putative hydrogenase maturation protease (9). My data suggest that Fre and Vhx are not able to substitute for the role of Frh and Vht in the Δfrh and $P_{tet}vht$ mutants, respectively. Thus, they are not functional under the conditions tested.

5.2.4 *M. barkeri* hydrogenases are dispensable during methylotrophic growth

The presence of H₂-independent F₄₂₀H₂:heterodisulfide (Fpo) and Fd_{red}:heterodisulfide (unidentified Fd_{red} oxidoreductase) electron transport chains in *M. barkeri* suggested that hydrogenases might be dispensable during growth of this organism using methanol. Thus, in Chapter 4, I attempted deletion of all five hydrogenases in *M. barkeri*, Fd_{ox}-dependent Ech, F₄₂₀-reducing Frh and Fre, and MP-dependent Vht and Vhx (14). We were able to isolate this quintuple

hydrogenase deletion mutant using methanol as the growth substrate, corroborating the branched nature of *M. barkeri* energy-conservation system.

5.2.5 All three types of hydrogenases are needed for growth of *M. barkeri* via the CO₂ reduction pathway

Deletion of Ech, Frh and/or Vht prevents growth of *M. barkeri* on H₂/CO₂. This is consistent with the proposal that all three electron carriers (Fd_{ox}, F₄₂₀ and MP) reduced by these hydrogenases are needed for CO₂ reduction to CH₄ (20).

5.2.6 Ech and/or Frh hydrogenases mediate repression of methyl oxidative pathway

A previous study had suggested that H₂ represses the methyl oxidative pathway (16). However, the quintuple hydrogenase deletion mutant is able to bypass this repression and grow methylotrophically on methanol plus H₂/CO₂, implicating involvement of hydrogenases in this metabolic regulation. More specifically, Ech and/or Frh hydrogenases might be responsible for this inhibitory effect, because the *vht*⁺ Δech *frh* mutant can oxidize methanol methyl group to CO₂, to obtain reducing equivalents for biosynthetic reactions.

5.2.7 Hyp proteins are essential for maturation of Ech hydrogenase

In Chapter 4, we provide experimental evidence for the hypothesis that Hyp proteins are involved in post-translational modification of [NiFe] hydrogenases in *M. barkeri* (2, 9). Unlike *ech*⁺ Δfrh *fre* *vht* *vhx* strain, the *ech*⁺ Δhyp *frh* *fre* *vht* *vhx* mutant is unable to grow via the methyl respiration pathway

using Ech, suggesting that this hydrogenase is non-functional in the Δhyp mutant. Thus, Hyp proteins are essential for maturation of the [NiFe] Ech hydrogenase. *M. barkeri* Ech is functional, when expressed heterologously in the closely related species, *Methanosarcina acetivorans* (10). This implies that *hyp* operon of *M. acetivorans* encodes functional Hyp proteins (9).

5.2.8 Fpo or Frh is needed for aceticlastic growth

Methanogenesis from acetate does not require either Frh or Fpo (7); however, our results in Chapter 2 show that one of the two enzymes, but not both, is needed for growth on this substrate. We previously showed that mutations in the C-1 oxidation pathway prevent growth on acetate, presumably by blocking the production of reducing equivalents needed for biosynthetic reactions (21). The lack of growth of the $\Delta frh \Delta fpo$ double mutant on acetate medium suggests that these reducing equivalents must flow through either Frh or Fpo to allow growth.

5.3 FUTURE DIRECTIONS

5.3.1 Identification of H₂-independent branch of the Fd_{red}:heterodisulfide oxidoreductase system

The hydrogenase mutants lacking Ech utilize a H₂-independent Fd_{red}:heterodisulfide electron transport chain during methylotrophic growth. To identify the components of this pathway, we plan to perform microarray expression analysis in various Δech mutants; Δech , $\Delta ech frh$, $\Delta ech frh vht$ and $\Delta ech frh fre vht vhx$; and the isogenic parental strain. However, our experimental

approach relies on the assumption that this $\text{Fd}_{\text{red}}:\text{heterodisulfide}$ system is up-regulated in the absence of Ech in the cell. Therefore, to overcome this caveat, we could directly target some potential Fd_{red} oxidoreductases in *M. barkeri* for genetic analysis, like the putative $\text{Fd}_{\text{red}}:\text{heterodisulfide}$ HdrA1B1C1 (3). Also, it has been postulated that the F_{420}H_2 dehydrogenase (Fpo) might be involved in this H_2 -independent $\text{Fd}_{\text{red}}:\text{heterodisulfide}$ chain, in case a $\text{Fd}_{\text{red}}:\text{F}_{420}$ oxidoreductase channels electrons from Fd_{red} to F_{420} . To verify this, we could isolate a $\Delta fpo\ ech$ double mutant and test its phenotype on methanol as the growth substrate.

5.3.2 Determination of hydrogenase activity exhibited by each of the hydrogenases

Each of the three types of hydrogenases in *M. barkeri* contributes to its overall benzyl-viologen-dependent hydrogenase activity. In this study, we isolated a series of hydrogenase deletion mutants, including single, double, triple, quadruple and quintuple mutants. An estimation of hydrogenase activity of all these mutants would give us an idea of the activity exhibited by each of the hydrogenases individually within the cell.

5.3.3 Determination of functionality of the Fre and Vhx hydrogenases

Hydrogenase activity in the $fre^+ vhx^+ \Delta ech\ frh\ vht$ strain can be measured to test if *fre* and *vhx* operons encode functional hydrogenases. If not, we can complement this strain with *frhD* or *vhtD* prior to hydrogenase activity measurements (9). This would tell us if subunit D encoded by *frh* and *vht* operons

can process Frh and Vht hydrogenases, respectively. In case Frh is a functional hydrogenase, the *vht* mutation in the complemented strain, *frhD⁺ frh⁺ vht⁺ Δech frh vht*, would be lethal to the cell, as has been demonstrated in the *P_{tet}vht* and *Δech P_{tet}vht* strains. Thus, an alternative way to test Frh functionality would be to introduce *frhD* in the *frh⁺ Δfrh* single mutant and then test F₄₂₀-dependent hydrogenase activity.

We also plan to investigate the role of Frh and Vht as potential regulators of hydrogenases in *M. barkeri*. To this end, *uidA* reporter gene fusions to the promoters of all hydrogenases will be integrated into the chromosome of *Δfrh* and *Δvht* mutants. Subsequently, we will determine β-glucuronidase activity in parental and mutant strains to find out differences in expression of hydrogenases between the two strains.

5.3.4 Testing functionality of *M. acetivorans* hydrogenases by complementation with *M. barkeri* hydrogenase deletion mutants

The non-hydrogenotrophic *Methanosarcina* species, *M. acetivorans*, encodes Frh, Vht and Vhx hydrogenases. While previous studies have implicated that these hydrogenases are not expressed within the native host, they contain all the structural and catalytic residues that are present in *M. barkeri* hydrogenases (9, 10). Thus, to test their functionality, we plan to express them in *M. barkeri* quintuple hydrogenase deletion mutant using the tetracycline-regulated *PmcrB(tetO1)* promoter and then determine their hydrogenase activity. This strategy might work for Vht, but not for Frh and Vhx. This is because presence of Frh in a *Δvht* mutant is lethal to the cell and Vhx may not encode a

functional hydrogenase without *vhtD*. Therefore, *M. acetivorans frh* operon can be introduced into *M. barkeri* Δfrh *fre* double mutant, which is unable to grow on H₂/CO₂ due to loss of Frh. If functional, *M. acetivorans* Frh would allow growth on this substrate and the complemented strain would display F₄₂₀-dependent hydrogenase activity. To test functionality of *M. acetivorans* Vhx, we can introduce *vhx* operon along with *vhtD* in the quintuple *M. barkeri* mutant and then test hydrogenase activity.

5.3.5 Testing aceticlastic Fd_{red}:heterodisulfide electron transport chains of *M. acetivorans* and *M. barkeri*

M. acetivorans Fd_{red}:heterodisulfide aceticlastic chain is postulated to comprise of the Na⁺-pumping Fd_{red}:MP oxidoreductase Rnf (3, 12), whereas, *M. barkeri* is proposed to utilize Ech and Vht hydrogenases to channel electrons from Fd_{red} to MP in this chain (15, 16). These proposals are consistent with the inability of *M. acetivorans* Δrnf , *M. barkeri* Δech and *M. barkeri* Δvht mutants to grow using acetate. However, to conclusively prove these electron transport pathways, we plan to reconstruct the Rnf-containing chain in the *M. barkeri* quintuple hydrogenase mutant by introduction of *rnf* operon into its genome; and the Ech/Vht H₂-cycling pathway in *M. acetivorans* Δrnf mutant by introducing *ech* and *vht* in its chromosome. Subsequently, we can test growth of the complemented strains on acetate. It is important to note that *M. barkeri* is missing the *rnf* operon, whereas, *M. acetivorans* lacks the *ech* operon and does not express its *vht* operon (8, 9, 14).

CURRICULUM VITAE

GARGI KULKARNI

University of Illinois at Urbana-Champaign, Department of Microbiology
B420 Chemical and Life Sciences Laboratory, Urbana, IL 61801

Email: gargik@gmail.com

Cell: (217) 721-8408

EDUCATION

PhD in Microbiology, University of Illinois at Urbana-Champaign May 2010
Thesis Advisor: Prof. William W. Metcalf
GPA: 3.88/4

MS in Microbiology, University of Illinois at Urbana-Champaign May 2006
Thesis Advisor: Prof. William W. Metcalf
GPA: 3.85/4

MSc in Biotechnology, Indian Institute of Technology Bombay, India May 2004
Thesis Advisor: Prof. Narayan S. Puneekar
GPA: 9.37/10 (Second rank in department)

BSc in Microbiology, University of Delhi, India May 2002
GPA: 7.32/10 (Second rank in department)

RESEARCH EXPERIENCE

Graduate Research Assistant, UIUC 2004 - 2010

- *Energy conservation in methanogenic Archaea*: Employed genetic and biochemical techniques in the strict anaerobe *Methanosarcina barkeri* to unravel a different mode of energy conservation, called H₂-cycling, during methylotrophic growth of the organism. Our study provided the first direct experimental evidence for the occurrence of H₂-cycling, since its proposal in sulfate-reducing bacteria in 1981.
- *Analysis of hydrogenases in Methanosarcina species*: Isolated single, double, triple, quadruple and quintuple *M. barkeri* hydrogenase deletion mutants in various combinations. Currently, I am characterizing the mutants in terms of growth characteristics, methane production, hydrogenase activity and expression of various genes. The quintuple mutant will also be used for complementation studies with *M. acetivorans* hydrogenases to determine their functionality.

Masters student, IITB, India 2003 - 2004

- *Inhibition of Aspergillus niger Glutamine synthetase (GS) by phosphinothricin (PTT)*: Employed biochemical techniques and assays to determine kinetic parameters for *in vitro* inhibition of partially purified GS by PTT. These efforts were directed to enable usage of PTT resistance as a selectable marker in *A. niger*.

AWARDS AND HONORS

- Outstanding Teaching Assistant, UIUC Fall 2006
- Junior Research Fellowship
Council of Scientific and Industrial Research, India (offer declined) Jun 2004
- National Eligibility Test (Eligibility for Lectureship)
Council of Scientific and Industrial Research, India (offer declined) Jun 2004
- MSc in Biotechnology, Second rank, IITB, India May 2004
- BSc (Honors) in Microbiology, Highest Aggregate
Gargi College, University of Delhi, India May 2002, May 2001, May 2000
- BSc (Honors) in Microbiology, Second rank
University of Delhi, India May 2002, May 2001
- Best Student of Science
Gargi College, University of Delhi, India May 2001
- BSc (Honors) in Microbiology, First rank
University of Delhi, India May 2000
- AMI (Association of Microbiologists of India) Quiz Winner Mar 2000
- 87% in First Level National Mathematics Olympiad Contest 1995-1996

TEACHING EXPERIENCE

- *MCB 301, Experimental Microbiology* Fall 2006, Fall 2005
The course emphasized on fundamentals of microbiology. Experiments involved growth, isolation and identification of bacteria as well as application of genetic and molecular biology techniques. I was in charge of managing and conducting two lab sections of 24 students each. Other duties included holding office hours, grading lab reports & homeworks and proctoring exams.
- *MCB 150, Molecular and Cellular Basis of Life* Spring 2005
This course focused on molecular and cellular biology of prokaryotes and eukaryotes. I was in charge of managing discussion sessions for three sections of 24 students each. Other duties included holding office hours, grading project reports & homeworks and proctoring exams.

POSTERS & PRESENTATIONS

Presented Doctoral thesis research entitled “Analysis of Hydrogen Metabolism in *Methanosarcina barkeri* Fusaro” at following conferences and seminars:

Gordon Research Conference

- Poster Presentation Aug 2007

Allerton Research Conference

- Oral Presentation Oct 2007
- Poster Presentation Sep 2009, Sep 2008, Oct 2006, Oct 2005

Student Seminar, UIUC

- Oral Presentation Oct 2008, Mar 2007
